A Report to and for
the Sole Use of Cooperators
NOT FOR PUBLICATION

FOREWORD

SUGARBEET RESEARCH is an annual compilation of progress reports concerning incomplete research by Science and Education Administration investigators and cooperators who are engaged in sugarbeet variety and production research. The report has been assembled by Dr. John S. McFarlane, Technical Advisor for sugarbeet breeding. The report has been reproduced at the expense of the Beet Sugar Development Foundation, and is for the sole use of the cooperators. Much of the data has not been sufficiently confirmed to justify general release and interpretations may be modified with additional experimentation. The report is not intended for publication and should not be used for cited reference nor quoted in publicity or advertising. Reproduction of any portion of the material contained herein will not be permitted without the specific consent of the contributor or contributors.

The report presents results of investigations strengthened by contributions received under Cooperative Agreements between Science and Education Administration, U.S. Department of Agriculture, and the Beet Sugar Development Foundation; the California Beet Growers Association, Ltd.; the Farmers and Manufacturers Beet Sugar Association; and the Sugarbeet Research and Education Board of Minnesota and North Dakota.

Trade names occur in this report solely to provide specific information and do not signify endorsement by the U.S. Department of Agriculture or the Beet Sugar Development Foundation.

SUMMARY OF ACCOMPLISHMENTS, 1978

RESISTANCE TO BEET WESTERN YELLOWS--In 1977 the virus yellows resistance breeding program was modified so that germplasm selections and evaluations were made against BWYV infection and not the BYV-BWYV complex as previously done. This modification was made for several reasons: (1) BYV was being well controlled culturally by the rigid adherence to beet-free periods; (2) BWYV which is poorly controlled by beet-free periods or most existing cultural practices remained a common malady in commercial production of beets; and (3) when both BYV and BWYV were used for inoculum, the more severe BYV mask many of the effects of BWYV and little was actually known about the damage potential of western yellows, the extent of host-plant resistance, the importance of resistance to western yellows in existing resistant germplasm and cultivars, or of possible host-parasite interactions. In order to confirm and expand the knowledge obtained from the 1977 tests, the 1978 yellows tests were in part a repetition of these 1977 evaluations. The 1978 variety x BWYV tests are summarized in Tests 1378, 1478, and 1578 (pages A28 - A33).

The reaction of breeding lines and hybrids evaluated in 1978 ranged from about 5% loss for C17 to about 37% sugar yield loss for SP6822-0. As in 1977, host reactions to yellows as measured by sugar yield losses are highly variable with test CV's in excess of 30% and the need for LSD (.05) values to be greater than 5% loss. Scores based on severity of yellows symptoms 6 to 8 weeks after inoculation gave reasonably good estimates of host reactions. Even though considered susceptible, breeding lines or hybrids with a long history of development in California, e.g., US 75 (468), F66-64, F70-546H3, and US H7, are significantly less susceptible than several entries developed away from natural exposure to BWYV, e.g., SP6822-0 and US H20. On the other extreme, C17 and closely related lines, e.g., E737, show very mild symptoms and sustain relatively little loss. However, for all entries, these loss data are probably biased downward due to infection in the noninoculated checks (as was the case for the 1978 tests). These biases are probably particularly true for the susceptible entries. By the same token, the yield data presented for the noninoculated portion of these tests are probably biased in favor of the more yellows resistant entries. If infection could be prevented in the checks, it is visualized that the measured sugar yield losses due to BWYV infection in the most susceptible entries might approach 50%. These tests thus demonstrated that BWYV has great potential for reducing sugar yield in susceptible cultivars but that sufficient host-plant resistance is available to greatly reduce this vulnerability. R. T. Lewellen, I. O. Skoyen, and J. S. McFarlane.

RESELECTION IN O.P. VARIETIES FOR RESISTANCE TO VIRUS YELLOWS--The data in Table 1478 show the performance for yield and BWYV reaction for some of the O.P. lines being carried in the virus yellows resistance program. As can be noted, these breeding lines are somewhat different for yield performance and reaction to BWYV. Of special interest is the comparison between the entries designated Y730 and 468. Line 468 is an increase of the obsolete O.P. cultivar US 75 from which the current pollinators C13, C17, and C36 were derived. Line Y730 represents the sixth cycle of mass selection from BYV-BWYV inoculated, spaced plants of US 75. Although both Y730 and the C13 to C17 series started with US 75, they represent different selection programs.

During the selection of C13, as few as five plants survived one cycle of selection and other cycles had as few as 11 participants. Because this led to a narrowed base of virus yellows resistant germplasm, it seemed desirable to reselect from US 75 and to try to maintain a broader germplasm base. Of great interest also was a general re-evaluation of the mass selection procedure for identifying yellows resistant genotypes and for improving this population for yield performance in comparison to what had been already accomplished by the selection of C13. This reselection also was to serve as a check to determine the comparative progress in a number of other O.P. sources simultaneously being selected for yellows resistance. The results of the reselection from US 75 are summarized very briefly below:

| | <u>Sugar Yield (lbs/A)</u> | | | <u>Beet Yield (T/A)</u> | | <u>% Sucrose</u> | |
|------|----------------------------|-------------|---------------|-------------------------|-------------|------------------|-------------|
| | <u>Check</u> | <u>BWYV</u> | <u>% Loss</u> | <u>Check</u> | <u>BWYV</u> | <u>Check</u> | <u>BWYV</u> |
| Y730 | 14,300 | 12,540 | 12.2 | 43.9 | 40.0 | 16.3 | 15.7 |
| 468 | 12,290 | 9,450 | 23.0 | 38.9 | 31.5 | 15.8 | 15.0 |
| | ** | ** | ** | ** | ** | NS | * |

After six cycles of selection, the BWYV reaction of Y730 is approaching the reaction of the lines derived from C13, e.g., F77-36. These C13 derived lines represent an equal number of selections for yellows resistance as Y730. The decrease in loss to yellows has apparently been accomplished in very small increments (averaging about 2%/cycle of selection). The performance of the Y730 line has been significantly improved over that of 468 (US 75) and is equal or better than that of the C13 to C17 series under both noninoculated and inoculated conditions. Experimental hybrids with Y730 have been made and will be evaluated in 1979. These hybrid evaluations should indicate whether simultaneous improvements in Y730 have been achieved for combining ability and give a general appraisal of the ability of mass selection to improve combining ability. A parallel series of selections for yellows resistance were made in the O.P. varieties US 15 and US 56/2. The data in Table 1478 suggest that the selection Y726 derived from US 56/2 is now moderately yellows resistant (10.9% sugar yield loss) whereas Y723 derived from US 15 has remained quite susceptible (25.5% loss). R. T. Lewellen, I. O. Skoyen, and J. S. McFarlane.

PREDICTION OF REACTION TO BWYV--Three pollinators and two females with different levels of resistance to BWYV and their six possible hybrids were evaluated for reaction to BWYV (Test 1378). As demonstrated by the data extracted from Test 1378 and presented below, the reaction of a hybrid to BWYV (% sugar yield loss) appears to be essentially intermediate to the reaction of the two parents:

| <u>Entry</u> | <u>Description</u> | <u>% Sugar Yield Loss</u> | |
|--------------|----------------------|---------------------------|------------------|
| | | <u>Observed</u> | <u>(M + F)/2</u> |
| C17 | Pollinator of US H10 | 10.6 | |
| C64 | " " US H7 | 23.9 | |
| 546H3 | Female of US H10 & 7 | 16.9 | |
| US H10 | 546H3 x C17 | 13.8 | 13.7 |
| US H7 | 546H3 x C64 | 22.1 | 20.4 |
| LSD (.05) | | 5.2 | |

This same relationship also was observed in advanced generations of lines derived from two parents with different reactions as these data from Test 1478 show:

| <u>Line</u> | <u>Description</u> | <u>% Sugar Yield Loss</u> | |
|-------------|----------------------|---------------------------|--|
| | | <u>Observed</u> | <u>(P₁ + P₂)/2</u> |
| C17 | | 4.9 | |
| C01 | | 6.9 | |
| C64 | | 21.9 | |
| Y740 | 3rd Inc. (C64 x C17) | 15.3 | 13.4 |
| Y741 | 3rd Inc. (C64 x C01) | 15.0 | 14.4 |
| LSD (.05) | | 8.1 | |

The reaction to BWYV thus appears to be transmitted in an additive manner and the reaction of a hybrid can be predicted if the reactions of the individual parental components are known. R. T. Lewellen, I. O. Skoyen, and J. S. McFarlane.

COMBINING ABILITY EVALUATION OF INBRED LINES--In an evaluation of the relationship between single-cross and 3-way cross performance for sugar yield, it was found that the mean performance of 3-way crosses usually was not different from expectations based on the means of single crosses (pages A37 - A39). These tests did not indicate that epistasis was important in the lines tested. Thus, a test of inbreds for general combining ability should accurately predict their performance in various hybrid combinations. R. T. Lewellen, I. O. Skoyen, and J. S. McFarlane.

POPULATION IMPROVEMENT OF MONOGERM GERMPLASM--A comprehensive breeding program in which hybrid varieties are the end product requires that breeding populations with genetic variability be developed and that these populations be improved by effective selection programs. At Salinas, the breeding sources have more or less diverged into those that are self-fertile monogerm and those that are self-sterile multigerms. Population improvement, usually by mass selection, in the self-sterile, multigerm sources has been effective as demonstrated by the development of disease resistant pollinators, e.g., C17, C36, C31, etc. However, population improvement within the self-fertile monogerm sources has proven more difficult, partially because of the lack of random-mating between cycles of selection. To overcome this constraint, a number of monogerm, self-fertile, near-type-0, random-mating populations have been developed by incorporating the gene for genetic male sterility (a1a1). Consequently, population improvement is now feasible within the self-fertile, monogerm sources without the continued necessity to outcross to the more advanced self-sterile multigerm sources. In addition, it may be easier to develop and maintain greater genetic diversity between these germplasms than previously possible. Tests 278, 1078, 1378, 1578, 1778, and B678 summarize the results of field tests used to evaluate some of these self-fertile, monogerm random-mating populations. To this time, the improvement within these monogerm populations has been primarily by mass selection for combinations of adaption, disease resistance (virus yellows, Erwinia, etc.), and sugar yield as well as for improved type-0 and monogerm types. In a test (1578) inoculated with BWYV, several previously selected populations have

shown yellows resistance better than F70-546H3 and approaching that of C36. Populations selected for resistance to Erwinia soft rot were also significantly improved for soft rot resistance. Though by and large susceptible to powdery mildew, individual plants have shown desirable levels of resistance and a first cycle of greenhouse selection has been completed. In comparison with US H10B (Tests 1078, 1378, and B678), some combinations between CMS equivalents of improved random-mating populations and multigerm pollinators have produced hybrids with equal or better sugar yield. Although improved monogerm populations may not be directly useful for commercial hybrid production, these results suggest that parental lines with improved combinations of multiple disease resistance and combining ability can be extracted from these sources. R. T. Lewellen, I. O. Skoyen, and J. S. McFarlane.

COMPARISON OF S₁ AND TESTCROSS EVALUATION AFTER ONE CYCLE OF SELECTION IN SUGARBEET--Synthetics derived from a monogerm, self-fertile, random-mating population were compared in field trials to determine the efficacy of S₁ and test-cross (TX) evaluation procedures at discriminating S₀ genotypes for high and low sugar yield (SY) and % sucrose (pages A52 - A61). As compared to a corresponding but unimproved synthetic, the evaluation of S₁ families successfully identified both higher and lower performing genotypes for the traits in question. Significant changes of 11.3% and -9.8% for SY and 4.2% and -4.0% for % sucrose were obtained. The changes in performance were less in the corresponding synthetics produced on the basis of TX performance. Mass selection for increased SY was as effective as S₁ and TX selection as measured by the performance of the synthetics but was less effective at identifying S₀ genotypes with improved GCA for SY in hybrid combinations. After one cycle of selection, it appeared that S₁ evaluation was superior to TX evaluation for discriminating differences in S₀ plants for GCA as measured in test hybrids with the synthetics. R. T. Lewellen and I. O. Skoyen.

RESISTANCE TO ERWINIA--A breeding program to select for resistance to Erwinia soft rot was continued in 1978. The first, second, or third cycles of selection were made in a number of breeding lines. In addition, approximately 200 breeding lines, parents, and hybrids were evaluated in three injury-inoculated tests. The Erwinia resistance program is summarized on pages A62 - A68 of this report. Results from this program showed that a broad germplasm base is being successfully converted to a significantly higher level of resistance. R. T. Lewellen, E. D. Whitney, and I. O. Skoyen.

FUSARIUM STALK BLIGHT RESISTANCE--Seed increases were made of 25 stalk blight resistant selections from a backcross of the susceptible C563 inbred to the moderately resistant NB1 inbred. Resistant segregates were also found within the C563 inbred. A resistant CMS line from a cross between NB1 CMS and C563 will be used to produce CMS equivalents of the resistant inbreds. A group of 35 lines were evaluated at Salem, Oregon in 1978. Stalk blight ratings ranged from 0 for two of the resistant selections to 3.6 for the susceptible 5564 monogerm inbred (0 = no disease to 4 = dead plant). J. S. McFarlane.

GERMPLASM PRESERVATION--Seed samples of all wild Beta species maintained by SEA sugarbeet researchers were assembled at Salinas and catalogued. Seed increases were made of most seedlots in the Vulgares section. A wild species nursery was grown and descriptions were recorded for each representative of the various species. J. S. McFarlane.

INTERSPECIFIC HYBRIDIZATION STUDIES--Transmission rate of nematode resistant factor from the alien monosomic addition lines of sugarbeet was low in all instances. Most of the progeny with resistance contained 19 chromosomes, with an average frequency of 10.52% through ovule and 0.025% through pollen. Diploid nematode resistant progeny were isolated only at 0.046% frequency. Nematode resistance transmission rates of the progeny of selection 51501 varied from 5.3% to 21.4%, but the overall transmission rate remained the same as that of the parent, i.e., 13.3%. Both the resistant and susceptible progenies were found to have a similar category of meiotic chromosomal abnormalities, which indicated that transmission of nematode resistance could be independent from the bridge formation mechanisms. From the triploid progeny with the resistance, selection 61202, seedlings with chromosome numbers of 18, 19, 20, 26, and 27 have been obtained. None of these single chromosome number groups were completely resistant to cyst nematode. M. H. Yu.

FIELD EVALUATION OF ROOT TOUGHNESS (ROOT FIBER CONTENT)--Two year's data on root toughness in representative breeding lines and varieties have shown that environmental influences are significant. The mean toughness probe value was 20.1 foot pounds pressure in 1977 compared with 1978 values of 22.5 in Test 1 and 23.2 in Test 2, respectively. Significant differences between and within varieties were again observed in 1978. Root selections for both high and low fiber content based on probe values were made in a test seeded in May 1978. I. O. Skoyen and R. T. Lewellen.

ABSTRACTS OF PAPERS PUBLISHED OR APPROVED FOR PUBLICATION, 1978

DUFFUS, JAMES E. Beet free periods holds beet yellowing viruses in check. The Sugar Producer 4(1):10-15. 1978.

The yellowing virus diseases are serious hazards to stable production of beet and numerous other crops throughout the world. Since the dawn of agriculture, man has accepted these diseases as being induced by natural factors such as early ripening, drought, excessive moisture, nutritional deficiencies, or soil conditions. The implementation of beet free periods in California beet growing districts since 1968 has dramatically increased sugar production.

DUFFUS, J. E. Legume yellows virus, a new persistent aphid-transmitted virus of legumes from California. Phytopathology (In press). 1979.

Legume yellows virus, a recently discovered virus, which has host range and vector characteristics similar to pea leaf roll virus (PeLRV) and other legume yellowing viruses, has been found to be widespread in California legumes. It is transmitted in a persistent manner by Acyrtosiphon pisum and A. solani to a large number of leguminous species including Pisum sativum, Trifolium incarnatum, T. subterraneum, Vicia faba, Cicer arietinum, Medicago sativa, and Glycine max, but not to over 30 species in 13 nonleguminous families tested. Purified preparations proved to be infectious when fed by aphids through membranes and contained mono-disperse icosahedral particles approximately 25 nm in diameter. The virus is not identical to other legume infecting yellowing viruses such as PeLRV or subterranean clover red leaf viruses (SCRLV), but would appear to be very similar. The virus differs markedly from beet western yellows virus (BWYV) in host range and vector specificity but was shown to be closely related in reciprocal infectivity neutralization tests.

DUFFUS, JAMES E. Beet yellow stunt virus. CMI/AAB. Descriptions of Plant Viruses (In press). 1979.

Beet yellow stunt, a potentially destructive yellows-type virus disease of sugarbeet and lettuce, is recognized as being distinct from other yellowing diseases affecting these crops. Sowthistle is the principal reservoir host of the virus and of the most efficient vector, Nasonovia lactucae. The disease is widespread and abundant on this host in California throughout the year. Spread in susceptible crops tends to be marginal; i.e., the disease incidence is high in rows adjacent to areas where sowthistle is prevalent, but becomes progressively less with increased distance from the virus source. Host range of the virus seems limited, but it can induce serious damage to infected sugar beet and lettuce. The virus has not been transmitted mechanically or by seed, but is transmitted in a semipersistent manner by N. lactucae, Myzus persicae, and Macrosiphum euphorbiae.

DUFFUS, JAMES E. Curly top virus control. Proc. IX International Congress of Plant Protection (In press). 1979. (Abstract)

Beet curly top virtually destroyed the sugar beet industry in the western United States following World War I. The disease was the principal limiting factor to sugarbeet production from the early 1900's until World War II. Curly top has been held to less than catastrophic proportions by a complex

control program involving a number of facets of agriculture and which includes the use of: 1) cultivars resistant to the virus; 2) cultural practices to delay infection; 3) vector control in the crop; 4) vector control in non-crop production areas; 5) reduction in leafhopper breeding areas; 6) and reduction in virus sources. In spite of the effective reduction of economic losses induced by curly top over the past several years, the disease is still present and changing along with the ecology of the California production areas. These changes demand constant attention to the present control procedures as well as to future ones.

DUFFUS, J. E. and G. M. MILBRATH. Natural occurrence and distribution of beet western yellows virus in soybean. Amer. Phytopath. Soc. Phytopath. News 12:170. 1978.

In an earlier report, it was established that soybeans, (Glycine max) were susceptible to beet western yellows virus (BWYV). To determine if BWYV is of potential economic significance in midwestern and southern soybean production areas fields and demonstration plots of susceptible soybean cultivars were sampled and indexed for the natural occurrence of BWYV. Positive recoveries were obtained from soybeans and/or other susceptible hosts in Illinois, Indiana, Michigan, Mississippi, Texas, and Wisconsin. Infected plants were chlorotic with yellowing symptoms or in other cases symptomless. The legume isolates of BWYV were similar to sugarbeet and crucifer isolates when tested by infectivity neutralization, ELISA serology and host range. The distribution of BWYV and other serologically related viruses in diverse economic crops raises the possibility that new serotypes adapt to new plant hosts. This is the first report of the natural occurrence of BWYV in legumes in North America.

ESAU, KATHERINE and LYNN L. HOEFERT. Hyperplastic phloem in sugarbeet leaves infected with the beet curly top virus. Amer. J. Bot. 65(7):772-783. 1978.

Electron microscopy of sugarbeet leaves infected with the beet curly top virus confirmed earlier findings by light microscopy that the hyperplastic phloem consists mainly of sieve elements that are more or less abnormal in structure. Some parenchyma cells and occasional companion cells may be present. The hyperplastic phloem develops in the place of normal phloem and sometimes in the adjacent ground tissue and the xylem. The sieve elements vary in shape and may be haphazardly arranged. The protoplasts of the sieve elements have the usual characteristics of this type of cell. The sieve element plastids develop from chloroplasts if the hyperplasia occurs in chloroplast-containing parenchyma cells. The cell walls have sieve areas that often are less well differentiated than those of normal sieve elements. The hyperplastic growth in the phloem of curly top diseased plants is discussed with reference to plant tumors induced by certain other plant viruses.

FALK, B. W., J. E. DUFFUS, and T. J. MORRIS. Genomic masking responsible for dependent aphid transmission of a virus in association with BWYV. Amer. Phytopath. Soc. Phytopath. News 12:194-195. 1978.

Lettuce speckles mottle virus (LSMV) is a mechanically transmissible, unstable plant virus. LSMV has been found in mixed infections with beet western yellows virus (BWYV) in lettuce, sugarbeets and spinach. When in the mixed infection, LSMV is transmissible by the green peach aphid, Myzus persicae Sulz.,

in a persistent, circulative manner. It has been demonstrated that mechanically transmitted LSMV has a very short longevity in vitro, is susceptible to low concentrations of ribonuclease A, and is very efficiently transmitted after phenol extraction of infected tissue. These characters are typical of unstable viruses. When in the mixed infection with BWYV, LSMV become aphid transmissible, is somewhat more stable and exhibits the serological (coat protein) properties of BWYV. In addition, the aphid transmitted LSMV from the mixed infection has a much wider host range than mechanically transmitted LSMV. These data suggest that LSMV is a member of a naturally occurring, previously unrecognized, group of plant viruses that survive and are dispersed in nature as a result of the genomic masking phenomenon.

FALK, B. W., T. J. MORRIS, and J. E. DUFFUS. Lettuce speckles mottle virus - evidence for the presence of replicative structures. Amer. Phytopath. Soc. Phytopath. News 12:148. 1978.

Lettuce speckles mottle virus (LSMV) has many properties similar to those reported for the carrot mottle group. It is unstable, possessing a short longevity in vitro, is highly susceptible to ribonuclease A, and is very efficiently transmitted from phenol extracted tissue. Particles similar to carrot mottle virus (50-70 nm membrane-bound spheres) were observed in cell vacuoles when infected tissues were examined with the electron microscope. Attempts to purify LSMV revealed that a gentle method of purification, consisting only of clarification with bentonite and differential centrifugation, was necessary to preserve infectivity. However, bentonite clarified preparations contained largely LSMV specific double-stranded RNA (ds-RNA) of 2.7×10^6 daltons which was only infectious upon melting. LSMV infectivity resides predominantly with single-stranded RNA. A LSMV specific ss-RNA with an apparent molecular weight of 1.4×10^6 daltons was also isolated from the infectious preparations and is believed to be the infectious viral nucleic acid. These results suggest isolation of a replication structure from LSMV infected tissue. Due to the similarity of the 50-70 nm spherical particles to replication structures for other viruses it is proposed that for LSMV these structures are not virus particles but may be sites of LSMV replication.

FALK, B. W., J. E. DUFFUS, and T. J. MORRIS. Transmission, host range and serological properties of the viruses causing lettuce speckles disease. Phytopathology (In press). 1979.

The speckles disease is caused by a virus complex affecting lettuce, sugarbeets, and spinach in the Salinas and Pajaro Valleys of California. The complex consists of two viruses, beet western yellows virus (BWYV) and lettuce speckles mottle virus (LSMV). Both viruses are transmitted by Myzus persicae, the green peach aphid, in a persistent manner; however, LSMV is only aphid transmissible when in a mixed infection with BWYV. The LSMV is mechanically transmissible and when separated from BWYV by mechanical transmission it loses its aphid transmission character. The host range of LSMV is expanded when it is transmitted by aphids from mixed infections as compared to mechanical inoculation. Lettuce speckles mottle virus exhibits a serological relationship to BWYV when in mixed infections, and the stability of LSMV in vitro is increased in sap from speckles virus complex infected plants as compared to those only infected with LSMV. These data suggest that genomic masking of LSMV by BWYV coat protein occurs as result of the mixed infection.

FALK, B. W., T. J. MORRIS, and J. E. DUFFUS. Unstable infectivity and possible replicative structures associated with lettuce speckles mottle virus. Virology (In press). 1979.

Lettuce speckles mottle virus (LSMV) is an unstable virus, susceptible to short periods of aging in vitro and low concentrations of RNase. Infected leaves extracted using phenol yielded greater infectivity than comparable tissue extracted with buffer. No typical virus particles were observed in infected tissues or semi-purified preparations, but 50-70 nm spherical membranous particles were observed associated with the tonoplast in vacuoles of infected cells. Nucleic acid analysis using polyacrylamide gel electrophoresis of infected tissue and LSMV semi-purified preparations revealed abundant double-stranded RNA (ds-RNA) in both preparations. In addition to ds-RNA, a species of disease specific single-stranded RNA (ss-RNA) was isolated from the LSMV semi-purified preparations. LSMV infectivity was associated with the ss-RNA fraction, however, the ds-RNA yielded infectious LSMV upon melting in dimethylsulfoxide. Quantitative isolation of ds-RNA from whole tissue and semi-purified preparations showed the majority of the ds-RNA to be recovered from the semi-purified fractions. Sucrose and cesium chloride density gradient centrifugation suggested that the ds-RNA was associated with a relatively small structure of a low buoyant density.

HURT, LESLIE C., ROBERT D. BARRY, and JOHN S. MCFARLANE. USSR Sugar - Today and tomorrow. Foreign Agricultural Service, USDA, FAS M-284, 15 pages. 1978.

This publication focuses on the economic and institutional features of the Soviet sugar industry. It is based on a trip to the Soviet Union in October 1977 by a United States Department of Agriculture Sugar Beet and Sugar Team. The trip was taken under the U.S.-USSR agreement for exchange of information, and was the first visit of an economic sugar team from the United States to the Soviet Union. The members of the team were Leslie C. Hurt, team leader, Foreign Agricultural Service; Robert D. Barry, Economics, Statistics, and Cooperatives Service; (formerly Economic Research Service) and John S. McFarlane, Science and Education Administration--Agricultural Research (formerly Agricultural Research Service).

The trip was made during the period October 10-28, 1977. The itinerary included Moscow, Kiev, Voronezh, Kishinev, Krasnodar, and producing areas in the Ukraine, Russian Soviet Federated Socialist Republic (RSFSR), and Moldavia. Meetings were held with officials of the Ministry of Agriculture, Ministry of Food and Industry, and Prodintorg (the State Trading Organization). Various collective and state farms and processing plants were visited.

LEWELLEN, R. T., J. S. MCFARLANE, and I. O. SKOYEN. Registration of 11 germplasm lines of sugarbeet. Crop Sci. 18:1100-1101. 1978.

The 11 breeding lines C01, C31, C04, C22, C10, C718, C718 CMS, C705, C705 CMS, C706, and C706 CMS are described.

LEWELLEN, R. T., I. O. SKOYEN, and J. S. MCFARLANE. Registration of three sugarbeet germplasm lines. Crop Sci. 18:1099-1100. 1978.

The three germplasm lines C773, C789, and C789 are described.

LEWELLEN, R. T., I. O. SKOYEN, J. S. MCFARLANE, and E. D. WHITNEY. Release of sugarbeet germplasm combining multiple-disease resistance. USDA-SEA-AR, July 6, 1978.

Eight germplasm lines of sugarbeet were released to sugarbeet breeders as sources of resistance to virus yellows, beet mosaic, curly top, powdery mildew, and Erwinia soft rot. These lines were designated as C779, C779 CMS, C16, C16 CMS, C19, C19 CMS, C43, and C32.

MCFARLANE, JOHN S. Sugarbeet variety development. California Sugar Beet Annual Report, pg. 36-38. 1979.

This popular article traces the history of variety development, discusses sugarbeet breeding methods, and describes the attributes of our present USDA developed varieties.

MILBRATH, G. M. and J. E. DUFFUS. Solanum yellows virus, an apparently distinct member of the luteovirus group. Amer. Phytopath. Soc. Phytopath. News 12:170. 1978.

A yellowing type virus, referred to as Solanum yellows virus (SYV), was isolated from naturally infected Solanum carolinense. It is transmitted in a persistent manner by Myzus persicae, but not Acyrtosiphon pisum. It appears distinct from other luteoviruses in its affinity to the Solanaceae and its yellowing type symptoms on susceptible hosts. In addition to S. carolinense the virus has been transmitted to and recovered from Datura metel, Nicandra physalodes, Nicotiana clevelandii, N. rustica, Physalis floridana and P. wrightii. Of over 40 non-solanaceous hosts tested none have been susceptible. SYV was purified from infected N. clevelandii leaf and stem tissue. The virus sedimented at the same rate in density gradients as the ST-1 strain of beet western yellows virus (BWYV). Preparations from the opalescent zone contained icosahedrons of the same size as BWYV. Neutralization of infectivity and ELISA serological tests with antisera to BWYV, and the RPV strain of BYDV demonstrated that SYV is related to these viruses. Based on this evidence, SYV appears to be a distinct naturally occurring yellowing virus. Its importance and distribution are unknown. The natural occurrence of luteoviruses in diverse plant species has raised questions about potential virus interactions as well as epidemiological considerations.

WHITNEY, E. D. and R. T. LEWELLEN. Registration of two sugarbeet parental lines. Crop Sci. 18:920. 1978.

Two parental lines, C02 and C36, with high levels of resistance to Erwinia soft rot are described.

YU, M. H. Meiotic behavior of a disomic nematode-resistant sugarbeet. Crop Sci. 18:615-618. 1978.

A disomic ($2n = 18$) sugarbeet (Beta vulgaris L.), selection 51501, resistant to cyst nematode (Heterodera schachtii Schm.), was recovered from the progenies of resistant alien addition lines. Meiosis of this plant was not normal and

gave univalents, laggards, fragments, bridges, unequal chromosome distribution, restitution nuclei, and carry-over AI bridges. Two heterozygous paracentric inversions were evident. These aberrations were not necessarily related to the nematode resistance. Nuclear restitution occurred in either the first or second meiotic division, or both; consequently, diploid and tetraploid gametophytes were produced. More than 25% of the pollen aborted. The preliminary findings showed that nematode resistance could have been transmitted to the progenies through the pollen and ovules at an equally low rate (13%). A multiple gene hypothesis of three complementary dominant genes was proposed to interpret the phenomenon of the low frequency transmission of nematode resistance.

BOLTING AND VARIETY TRIALS, SALINAS, CALIFORNIA, 1977-78

Location: USDA Agricultural Research Station

Soil type: Sandy loam (Chualar series).

Previous crops: 1977-78 Sugarbeet test areas, Spence Field:
Block 1 - north, fallow 1975-1976; sugarbeet trials, 1974.
Block 2 - north, fallow 5 years.

Fertilizer used: Preplant: Dolomite (equivalent to 105% CaCO₃), as needed, was broadcast at a rate of 1100 lbs/A and disced in about 6 inches deep. All test areas had 287 lbs/A 5:20:10 applied broadcast and chiseled in before listing in October 1977. Prior to seeding, 340 lbs/A ammonium sulfate was Bye Hoe incorporated into a 9-inch band on the beds.

Supplemental nitrogen: Two applications, as sidedressed ammonium sulfate at rates ranging from 334 to 420 lbs/A.

Total fertilization (lbs/A): $\frac{N}{235} \quad \frac{P_2O_5}{57} \quad \frac{K_2O}{29}$

Inoculation dates (1978): Tests 1378 through 1578: May 11, with BWYV.
Test 1778: July 19 with a suspension of Erwinia
bacterium.

Irrigation: By either furrow or sprinkler system as required at 7-14 day intervals except during stand establishment when frequent light sprinkler irrigations were used.

Diseases and insects: Natural virus yellows infection was moderate throughout tests seeded between November 11, 1977 and February 1, 1978 (Tests 178 through 1278, Field 1). Natural infection appeared light in tests seeded between February 28 and May 4, 1978 (Field 2).

Inoculated BWYV tests 1378 through 1578 were sprayed twice with 1.7 pints/A Meta Systox R, (1) on May 12, 1978 for control of BWYV aphid vector and (2) on June 21, 1978 for control of aphid. Non-inoculated test plot areas were sprayed with 1.7 pints/A Meta Systox R for aphid control between June 5 and June 21, 1978.

A severe infestation of salt marsh caterpillar was controlled with an application of Lannate at 1 lb/A a.i. on August 19, 1978.

Powdery mildew was moderately severe in 1978 where it was not controlled and appeared first (early June) in the earliest seeded tests. Two spray applications of sulfur at rates of 15-17 lbs/A, on designated test areas, about June 15 and about July 30, 1978, provided good control of powdery mildew infection.

Downy mildew was moderately severe in 1978 and caused yield and sucrose losses in susceptible lines and their hybrids, for example in 604-13, 604-15, and their hybrids.

Natural infection of Erwinia soft rot was light and had minimum effect on yield in 1978.

Sugar analysis: Determined from two samples per plot of approximately 10 roots each or 25-40 lbs of roots at the sugar analytical laboratory, U. S. Agricultural Research Station, Salinas, California.

Remarks: The assistance of Dr. F. J. Hills and Ms. Patricia Thomas, University of California at Davis, in the analysis of test data is gratefully acknowledged.

1/ Rust was allowed to develop by natural infection. At incipient symptoms, control plots were sprayed with Plantvax at 3.5 lbs. ai/A on August 8 and 23. The severity of rust remained low throughout the season but from mid-September to harvest, rust incidence was relatively more severe in the uncontrolled plots. At this time there also was an obvious difference between C36H8 and Mono-Hy D2. Other than a low level of erwinia soft rot, the test appeared relatively disease free. Also see page A40, 1977 "Bluebook" Report.

2/ Rust treatments were not significantly different. Variety x rust interactions did not occur.

3/ % roots with erwinia soft rot at harvest. Diseased roots were weighed but not included in sugar sample.

Combining Ability Evaluations of Advanced Disease Resistant Inbreds

R. T. Lewellen, I. O. Skoyen, J. S. McFarlane

Inbred lines extracted from breeding populations need to be evaluated for combining ability (CA) by some efficient and systematic procedure. However, because of the limited scope of the applied breeding program at Salinas, a systematic procedure has not always been used. Traditionally we have been primarily concerned with the development of good monogerm type-0 lines that possess disease resistance. Thus, relatively few advanced lines have been entered into CA tests at any one time. However, before these lines are released, some information on their CA is desirable. It also would be desirable to obtain this information prior to developing their CMS equivalents. Insufficient outcrossing has occurred with some of these S^f lines to permit the use of the standard red-beet topcross test. Therefore, the use of 3-way crosses with a common CMS line and topcross tester or pollinator, i.e., (CMS x type-0 inbred) x pollinator, to evaluate CA may be technically easier and more efficient than to use single cross (type-0 inbred x pollinator) evaluations.

To determine the relationship between single cross and 3-way cross performance, a set of four inbred lines and their six possible F_1 hybrids was crossed to two pollinators. The four inbreds chosen for these tests have equivalent CMS counterparts and are typical of the kinds of lines developed in the Salinas program. If epistasis is not a major factor in sugarbeet hybrid performance, then the mean of the two single crosses should be equal to their related 3-way cross; i.e., $[(A \times \text{pollinator}) + (B \times \text{pollinator})] / 2$ should be equal to $(A \times B) \times \text{pollinator}$. If deviations from this relationship do not occur, then single cross performance can be used to accurately predict 3-way cross performance for sugar yield. Conversely, if the CA performance of inbreds in a set of 3-way crosses involving a common CMS and pollinator and their common CMS x pollinator single cross is determined, then the performance of any of the possible single cross or 3-way cross combinations can be predicted. If deviations from the single cross vs. 3-way cross relationship do occur and are of sufficient magnitude, then epistasis as a factor in sugarbeet hybrid performance is suggested and the relative performance of inbred lines in hybrid combination will be more difficult to predict.

The results of the single cross and 3-way cross evaluations are given in Tests 478 and 878 from Salinas and B478 from Brawley. In addition, a summary of these tests for actual and predicted sugar yield is presented on page A37. A CA evaluation test for eight new advanced inbreds from the yellows resistance program is summarized in Test 978.

The summary on page A37 shows that the average sugar yield of the 3-way hybrids for the C17 and C31E1 pollinators were 101.6 and 102.0%, respectively, of the predicted values based on the single cross performances. For these tests, only one 3-way hybrid consistently deviated significantly. However, evidence based on hypocotyl color frequency for this hybrid, Y731H30 = (C706 x C536) x C31E1, suggested that the seed source was switched with another unknown hybrid; this deviation is probably not due to epistasis. Because of the probable lack of deviations due to epistasis, the data based on these

four inbreds suggest that 3-way crosses can be satisfactorily used to evaluate the CA of individual type-0 inbreds for sugar yield. Thus a set of n inbred lines can be evaluated by n 3-way hybrids when all are crossed to a common CMS and pollinator component. Furthermore, if the performance of the single cross between the common CMS and pollinator is known, it should be possible to accurately predict the relative 3-way performance of any two of the n inbreds. For example, if the relative performance is known for

| | |
|--------------------|--------|
| CMS x tester | = 100% |
| (CMS x A) x tester | = 110 |
| (CMS x B) x " | = 105 |
| (CMS x C) x " | = 90 |

then the predicted performance of

| | |
|------------|--------|
| A x tester | = 120% |
| B x " | = 110 |
| C x " | = 80 |

and the performance of the untested 3-way combinations would be predicted as

| | |
|------------------|--------|
| (A x B) x tester | = 115% |
| (A x C) x " | = 100 |
| (B x C) x " | = 95 |

The CA evaluation of a moderate number of advanced inbred lines generated in the disease resistance breeding programs could be accommodated by this type of systematic procedure. Not only would this procedure provide the necessary information on the CA of individual inbred lines, it would suggest how they would perform in various 3-way cross combinations, i.e., the type of hybrids grown commercially in California.

SUMMARY OF TESTS 478, 878, AND B478. OBSERVED AND PREDICTED 3-WAY HYBRID PERFORMANCE FOR SUGAR YIELD FROM SINGLE- AND 3-WAY CROSSES OF SUGARBEET GROWN IN 1978 AT SALINAS AND BRAWLEY, CA.

| Mean | 11,968 | 11,684 | 102.5 | 12,721 | 12,635 | 100.7 | 9,977 | 9,720 | 102.7 |

^{1/} O = observed or actual performance, P = predicted performance. Predicted performance of the 3-way hybrid, (A x B) x C, was calculated as the mean of the two corresponding single-crosses, (A x C) and (B x C).
^{2/} Deviation from 100% necessary for significance for specific comparisons at least at the 5% level = 7.2, 5.5, and 5.0% for tests 478, 878, and B478, respectively.

^{3/} Based on these field performance data and the ratio of red and green hypocotyl colors in greenhouse tests, there is some likelihood that the seed lot tested is actually a hybrid different from (C706 x C536) x C31E1.

| F value for entries ^{3/} | | | 6.9** | | 6.2** | | 4.3** | | 2.7** | 2.9** | 0.6 | 2.2* | | | |
| F value for F x M | | | 2.2* | | 2.8** | | 1.1NS | | 1.5NS | 1.8NS | 1.6 | 0.9 | | | |

1/Hybrid code number. In our conventional manner these 1977 seed increases would be listed as, e.g., 717H31 = (C562HO x C718) x C17 and Y731H31 = (C562HO x C718) x C31E1.

2/Means with a letter in common are not significantly different according to the F test. For bolting, powdery mildew on 7/17, and downy mildew on 4/26, the means for males are 1.4 vs. 1.6% (NS), ratings of 5.3 vs. 4.8 (**), and 1.1% vs. 1.2% (NS), respectively.

3/For bolting, powdery mildew, and downy mildew, the LSD and F values are for females.

VARIETY TRIALS, BRAWLEY, CALIFORNIA, 1977-78

Location: USDA-SEA, Imperial Valley Conservation Research Center

Soil type: Holtville silty clay loam

Previous crops: Cereals or fallow, 1977; Beets, 1975-6

Fertilization: Preplant: 100 lbs/A 11:48:0 and 100 lbs/A 46:0:0 (urea)
broadcast and disced before listing.

Sidedress: 100 lbs/A 46:0:0.

Total (lbs/A): N(103): P₂O₅(48): K₂O(0).

| B878 | 9/8 | 64 | 2 | 1 | 24 | " | " |
| B978 | 9/8 | 10 | 16 | 1 | 24 | Late Season | Rot Test |

*Watered up starting September 9, 1977.

**Rows 32" wide.

Irrigations: Sprinkled as needed to establish stand, then once following thinning. Furrow irrigated five times as needed up to May 10.

Thinned: September 30, 1977

Diseases and insects: Control measures as needed throughout growing season.

Herbicides not used. Sulfur applied twice for powdery mildew control.

Worms caused moderate defoliation in early May. Lannate used to control

beet army worms. Virus yellows probably light. Essentially no bolting.

Low incidence of root rot. At harvest a low infestation of mites was

present but Empoasca infestation was moderate and causing chlorosis;

variability for chlorosis suggested a differential in feeding preference or sensitivity to their toxin.

Harvest and sugar analysis: Plots were harvested with Holly's spike-wheel lifter. Roots from total plot were weighed and two six-to eight- root samples (20- to 30- pounds) removed. Sugar analyses were by Union Sugar. Root and sugar yields were adjusted for dirt and crown tare.

Remarks: Stands were consistently excellent. Test reliability should be good. No disease appeared to be severe enough at harvest to differentially reduce yields.

We wish to acknowledge the supervision of these plots by J. Robertson and C. Brown, I. V. Conservation Research Center, Brawley, CA, and Patricia Thomas, Davis, CA, for the statistical analysis.

^{1/} Syn 1 populations were synthesized from remnant S₁ seed. For TX evaluations, the single-cross C718CMS x C16 was used as the common tester. Selection intensity was approximately 20% for sugar yield (SY) and for % sucrose (%S) for both high and low performance. Self-fertile S₁ plants were recombined in isolation plots by harvesting seed only from genetic male sterile (aa) segregates.

Comparison of S_1 and Test-cross Evaluation
After One Cycle of Selection in Sugarbeet

R. T. Lewellen, I. O. Skoyen, J. S. McFarlane

When the end product of a breeding program involves hybrid cultivars, it is generally recognized that a good breeding program will have three distinctive phases: (1) development of divergent breeding populations with maximum genetic variation, (2) continuous improvement by an effective selection program, and (3) the identification of superior hybrids from the improved sources by an effective and systematic procedure. In our Salinas program, breeding populations have evolved into two broad, but not always divergent, types: (1) those possessing the S^f gene from which monogerm, type-0, seed bearing parents are to be derived and (2) those possessing self-sterility (S^sS^s) from which pollinators are to be derived. The population improvement program has largely been confined to the self-sterile sources because random mating after each cycle of selection is very difficult to obtain and control in most self-fertile sources. To overcome this problem, genetic male sterility (a_1a_1) has been introduced and relatively broadbased self-fertile, monogerm, type-0, random-mating populations have been developed. Thus, population improvement (recurrent selection) methods can be practiced in self-fertile sources and need to be evaluated. In addition, it is now feasible to use S_1 evaluation in addition to those intrapopulation improvement methods previously adaptable to self-sterile sources.

The theoretically effectiveness and efficiency of intrapopulation improvement methods have been published as have combining ability and gene action estimates in sugarbeet. However, realized progress with any breeding scheme largely depends upon the breeder's ability to identify superior genotypes. Selection methods need objective comparison for reliability in genotype evaluation. S_1 performance for genotype identification has proven effective in other crops, e.g., corn and sorghum. In an earlier study in sugarbeet (see 1976 and 1977 Reports on Sugarbeet Research), we investigated S_1 evaluation as a method of discriminating S_0 genotypes for sugar yield, sucrose percentage, and concentrations of NH_2-N , Na, and K. This is a preliminary report extending that study and compares performance and combining ability of synthetics derived after one cycle of selection. S_1 progeny evaluation is compared to test-cross progeny evaluation as a method to identify and sort genotypes for high and low performance.

Materials and Methods--The self-fertile, random-mating source population was designated 790 and was developed from bulk crosses involving a large number of self-fertile breeding lines. These inbreds had been developed in the curly top and virus yellows resistance breeding programs and were adapted to California. After a cycle of selfing and selecting for monogerm, the population was advanced by random mating. The source population segregated for genetic male sterility and S_0 plants would have been either A_1a_1 or a_1a_1 .

The following generalized procedure was used to obtain the cycle 1 (C1) synthetics:

| | |
|------|--|
| 1974 | CO seed planted in steckling nursery |
| 1975 | <div style="display: flex; justify-content: space-around; align-items: center;"> <div style="text-align: center;"> CMS tester ↓ TX </div> <div style="text-align: center;"> x Aa⊗ ↓ S₁ </div> </div> |
| 1976 | Progeny evaluation tests at Salinas (90 corresponding S ₁ and TX progenies + 10 check entries in adjacent tests) <div style="display: flex; justify-content: space-around; align-items: center;"> <div style="text-align: center;"> ↓ Remnant S₁ seed planted in steckling nursery ↓ S₁ </div> <div style="text-align: center;"> ↓ S₁ </div> </div> |
| 1977 | Intercross isolation plots (20% selection), seed from a ₁ a ₁ = C1 Syn 1, fertile (A ₁ -) plants outcrossed to C718H0 and C16H0 |
| 1978 | C1 vs. CO tests at Salinas and Brawley |

After the test-cross and S₁ progeny evaluations, selections (20% intensity) were made for high and low sugar yield based on S₁ or TX performance and high and low sucrose content based only on S₁ performance. In addition, a selection based on the best combined performance of the corresponding S₁ and TX progenies for sugar yield was made. The selected S₁ families were represented by an average of 22 plants, or approximately 400 plants were intermated to form the C1 syn 1 synthetics. An unselected synthetic check was produced by intermating plants from each of the 90 S₁ families evaluated. A synthetic derived by mass selection and the original 790 source population were included in the 1978 C1 vs. CO tests. In 1977 when the selected S₁ families were being recombined, hybrids with C718H0 and C16H0 were produced. The derived synthetics and hybrids were evaluated at Salinas and Brawley in 1978.

Results and Discussion--The results of the 1978 tests at Salinas and Brawley are summarized in the following table (page A55). The results of the comparisons among the synthetics derived by S₁ and TX evaluations are presented in greater detail by individual tests in the tables identified as Tests 1278-1, -2, -3, 1678-1, -2, 2078, and B578.

Two unselected populations or synthetics were included in these tests. The entry identified as 4790 is the original source population from which the S₀ plants were randomly drawn to produce the S₁ and TX progenies. Entry 7790C is the synthetic derived by random mating among all of the 90 evaluated S₁ families and was chosen as the check entry because it represented the array of genotypes sampled from 4790 for this selection study. Entry 7790C also would be in the same state of genetic equilibrium as the other synthetics and was produced under identical field conditions. Possibly these differences may account for 4790's performance being consistently better for sugar and beet yield (about 4%) than 7790C. If increased equilibrium contributes to better population performance, then part of the apparent sugar yield increase (9.4%) attributed to mass selection (entry 7790) may have resulted from this cause. Whatever the explanation, these data show that one cycle of mass selection from spaced S₀ plants of 4790 was nearly as effective at increasing population performance as was S₁ selection.

The synthetics derived on the basis of S_1 selection for high and low sugar yield were significantly higher (11.3%) and lower (-9.8%) for sugar yield than the check. These differences were due to changes in beet yield with sucrose content remaining essentially unchanged. The selection for high sugar yield based on TX performance also produced a significant increase in sugar yield (8.5%) and beet yield (8.4%), but the selection for low sugar yield did not greatly influence the performance of the derived synthetic in comparison to the check. The synthetics for high and low sugar yield derived by S_1 evaluation were separated by about 21% difference in sugar yield performance whereas those derived by TX evaluation were separated by about 10% difference in sugar yield. Thus, the S_1 evaluation appeared to be more effective than TX evaluation at discriminating S_0 genotypes that contribute to population sugar yield. The selection based on the best combined S_1 -TX progeny performance for sugar yield increased sugar yield by 6.4%.

The divergent selections for high and low sucrose content by S_1 evaluations were effective at increasing (4.2%) and decreasing (-4.0%) the sucrose content. However, these selections had an even greater influence on the root yield (-7.9 and 8.6%, respectively) so that the selection for high sucrose decreased gross sugar yield (-4.2%) and the one for low sucrose increased gross sugar yield (4.2%).

Supposedly both the S_1 and TX evaluations would identify genes for general combining ability. If so, the changes in general combining ability should be reflected in the performance of the synthetics per se and in hybrid combinations. As shown above, significant differences in the performance of the synthetics were produced by selection but such dramatic differences were not evident in the hybrid combinations tested. However, as in the performance of the synthetics per se, S_1 selection caused greater changes in hybrid performance than did TX selection. The results of these hybrid tests may be somewhat misleading and must be viewed as highly preliminary because the hybrids were produced from the fertile plants from the selected S_1 families and there had been no previous cycles of recombination.

In summary, after one cycle of selection in population 790, these preliminary results suggested that S_1 selection for sugar yield gave greater improvement in population yield than TX selection and was equal or better to TX selection for improving general combining ability. These results are consistent with those obtained with S_1 selection in population 791 which were previously reported. At least one of these synthetics will be used for additional cycles of selection to determine the practicality of using S_1 evaluation as an effective recurrent selection method for continued intra-population improvement.

SUMMARY OF RELATIVE PERFORMANCES OF C1 SYN 1 SYNTHETICS OF 790 PER SE FOR YIELD, 1978¹/

| Synthetic | Cycle ² / C0 Syn 1 Inc. source thru S1 Original source population | Sugar Yield (lbs/A) | | | | Beet Yield (tons/A) | | | |

| 7790G | C1 Syn 1 %S by S ₁ evaluation | 10,827c | 32.36d | 117 | 16.79a | 117 | 0.4 |
| 7790H | C1 Syn 1 LSY by S ₁ evaluation | 10,072d | 30.48e | 119 | 16.56ab | 119 | 0.7 |
| Mean | | 11,405 | 35.14 | 122 | 16.30 | 122 | 0.1 |
| LSD (.05) | | 556 | 1.80 | 9.3 | 0.40 | 9.3 | NS |
| C. V. (%) | | 5.5 | 5.8 | 8.6 | 2.8 | 8.6 | 458.7 |
| F value | | 11.6** | 12.7** | 6.1** | 4.6** | 6.1** | 1.7 |

^{1/}Syn 1 populations were synthesized from remnant S₁ seed. For TX evaluations, the single-cross C718CMS x C16 was used as the common tester. Selection intensity was approximately 20% for sugar yield (SY) and % sucrose (%S) for both high and low performance. Self-fertile S₁ plants were recombined in isolation plots by harvesting seed only from genetic male-sterile (a1a1) segregates.

TEST 1278-2. COMPARISON OF S₁ AND TEST-CROSS EVALUATION AND SELECTION:
C718HO x 790, SALINAS, CALIFORNIA, 1978

PERFORMANCE OF SUGARBEET LINES AND HYBRIDS SELECTED FOR RESISTANCE TO ERWINIA

R. T. Lewellen, E. D. Whitney, I. O. Skoyen

Breeding for resistance to soft rot of sugarbeet incited by an Erwinia was continued in 1978. Selection for resistance to soft rot was the primary objective in 15 breeding lines with concurrent selection pressure exerted for resistance to BWYV, downy mildew, powdery mildew and/or root size, shape, and sucrose content. In an additional nine breeding lines in which selection for BWYV was the primary objective, a late Erwinia inoculation was used to screen out highly soft rot susceptible genotypes. In injury-inoculation tests at Salinas and Spence, approximately 200 breeding lines and hybrids were evaluated for reaction to Erwinia.

Advanced soft rot resistant breeding lines were evaluated in hybrid combinations at Salinas, Brawley, and in cooperation with sugar company researchers. The hybrids with the C36 pollinator continued to have sugar yield performance characteristics similar to those with the C13 or C17 pollinators, e.g., US H9 and US H10 (See Tests 578, 778, 1378, B178, B278, and company tests in other sections of this report). A large semi-commercial increase of the C36H8 hybrid [C36H8 = (C562H0 x C546) x C36] was produced by the California sugar companies in 1978 and is being distributed to growers with the provisional name of US H10E. Because this C36 hybrid is being produced in 1979 in larger commercial quantities and is significantly changed from either the US H9 or US H10 hybrids in its reaction to Erwinia soft rot, a new hybrid designation will be made. An official USDA-SEA-AR release is being prepared that will designate the C36 hybrid cultivar produced after 1978 as US H11. Information from recent evaluations for reaction to Erwinia is briefly summarized in the following results and discussion.

As Table 1 shows, a moderate level of susceptibility to Erwinia has always been present in California cultivars and breeding lines. However, the damaging effects of Erwinia soft rot were not recognized until after US H9 and US H10 were grown commercially. C36, selected from C13, now possesses a higher level of resistance than previously provided by US 15, 56, or 75.

TABLE 1. REACTION OF BREEDING LINES TO ERWINIA

| <u>Line</u> | <u>Description</u> | <u>% Rot/Beet</u> | <u>% Resist. Beets</u> |
|---|---------------------|-------------------|------------------------|
| US 15 | O. P. cultivar | 12 | 77 |
| US 56 | " " | 10 | 83 |
| US 75 | " " | 15 | 68 |
| C64 | Pollinator of US H7 | 7 | 85 |
| C13 | " " US H9 | 55 | 21 |
| C17 | " " US H10 | 51 | 21 |
| C36 | " " C36H8 | 3 | 94 |
| Mean of 5 injury-inoculated tests, 1976-78. | | | |

Table 2 shows the improvement in soft rot resistance for each cycle of selection from C13 to C36. An additional (fourth) cycle of selection has been made which further reduced susceptibility.

TABLE 2. REACTION OF BREEDING LINES TO ERWINIA

| <u>Line</u> | <u>Description</u> | <u>% Rot/Beet</u> |
|--|----------------------------|-------------------|
| C13 | | 60 |
| E38 | 1 Cycle of selection | 25 |
| E38 | 2 Cycles of selection | 15 |
| C36 | 3 Cycles of selection | 3 |
| E36 | 4 Cycles of selection | 1 |
| E40 | 1 Cycle for susceptibility | 84 |
| Mean of 2 injury-inoculated tests, 1978. | | |

One or more selections for soft rot resistance have been made in other advanced or promising breeding lines (Table 3). Two cycles of selection have reduced the susceptibility of C17 to approximately one-fourth of the unselected lines value. A third cycle of selection was made in the C17 series in 1978 as were second cycles of selection in the C31 and Y41 lines. Each cycle of selection has approximately halved the damage caused by soft rot.

TABLE 3. REACTION OF BREEDING LINES TO ERWINIA

| <u>Line</u> | <u>Description</u> | <u>% Rot/Beet</u> |
|--|-----------------------|-------------------|
| C17 | | 52 |
| E37 | 1 Cycle of selection | 25 |
| E37 | 2 Cycles of selection | 12 |

| Y41 | | 23 |
| Y41E | 1 Cycle of selection | 10 |
| Mean of 2 injury-inoculated tests, 1978. | | |

Table 4 gives additional examples of the progress being made in selecting lines for resistance to Erwinia, particularly in combining it with other multiple disease resistant needs, e.g., curly top and virus yellows, and greater productivity.

| Mean of 2 injury-inoculated tests, 1978. | | |

Based upon inheritance of resistance studies and evaluation tests, it is now possible to fairly accurately predict the frequency of resistant and susceptible plants in hybrid combinations. The assumptions are that the frequency of resistant and susceptible plants in the parental lines can be accurately determined in inoculated tests, that one major host reaction gene is primarily responsible for host-plant resistance, and that this gene is completely dominant with the dominant allele conditioning a high level of resistance. Examples are provided in Table 5 in which parental lines are represented by R (resistant), I (intermediate), and S (susceptible) types. The R, I, and S values used are those observed from the evaluation of parental lines C36, 546H3, and C17, respectively.

TABLE 5. THEORETICAL FREQUENCY (%) OF SUSCEPTIBLE PLANTS IN HYBRID COMBINATIONS

| Seed Parent | Pollinator | | |
|----------------|------------|----|------|
| | R | I | S |
| R | 4 | 10 | 20 |
| I | 10* | 30 | 50** |
| S | 20 | 50 | 80 |

Values based on injury-inoculated tests at Salinas.

R = 4% susceptible plants, e.g., C36
 I = 30% " " , e.g., 546H3
 S = 80% " " , e.g., C17

* I x R = 10% susceptible plants is close to observed value for C36H8.

** I x S = 50% susceptible plants is close to observed value for US H10B.

For example, the R line has about 4% susceptible plants. The frequency of the recessive allele is then the square root of 0.04 or 0.2. Likewise, the frequencies of the susceptible or recessive allele for the I and S lines are approximately 0.5 and 0.9, respectively. The proportion of susceptible plants from any combination of these lines is then the product of their recessive gene frequencies. For example, two resistant lines equal to C36 would have $0.2 \times 0.2 \times 100$ or approximately 4% susceptible plants. The R x I hybrid combination would have $0.2 \times 0.5 \times 100$ or approximately 10% susceptible plants which is very close to the observed value for the C36H8 hybrid [C36H8 = 546H3(I) x C36(R)]. An I x S combination would have $0.5 \times 0.9 \times 100$ or about 50% susceptible plants which is very close to the observed value for the US H10B hybrid [US H10B = 546H3(I) x C17(S)]. A similar procedure can be used to estimate the frequency of susceptible plants in any hybrid. It should be pointed out, however, that this procedure estimates the frequency (%) of susceptible plants and not the DI or % rot/beet value usually used to compare varietal reactions and damage estimates. Normally the DI or % rot/beet value will be about half the value of the % susceptible roots.

Notes on *Erwinia* soft rot evaluations at Salinas and Spence:

The conditions for the Salinas test were superior to those for the Spence test (Test 1778) and should have better reliability. Test 1778 was grown on a variable plot of soil and differential growth rates are known to influence the severity of soft rot. In addition, downy mildew infection in Test 1778 was moderate in susceptible lines and it was sometimes difficult to distinguish the systemic symptoms of these two diseases.

The entry E640 should be nearly 100% susceptible to *Erwinia*. At Salinas, 1% of the plants were scored as resistant. At Spence, about 14% of the plants were scored as resistant, suggesting a higher frequency of escapes.

Erwinia soft rot development is known to be more severe under high temperatures. Therefore, it is probable that under the warmer conditions of California's interior valleys, the rot ratings would be higher.

In comparison with vigorous O.P. lines or hybrids, inbred lines may not give true disease ratings. Growth rates, whether due to environmental or genotypic causes, appear to influence rate of rot development. Thus, inbreds are probably scored as being more resistant than they actually are. Monogerm lines also are difficult to accurately score. If a resistant monogerm plant's apex is too severely damaged by injury-inoculation, the root will appear to be too severely damaged by *Erwinia* infection.

INTERSPECIFIC HYBRIDIZATION

Studies of Interspecific Hybridization in Beta Species

M. H. Yu

Transmission of Nematode Resistant Factor from the Alien Monosomic Addition Lines of Sugarbeet

During the past years a series of screening and selection had been conducted with the objective of transferring the nematode resistant factor from the wild beet, Beta procumbens, into sugarbeet via interspecific hybridization. The available alien monosomic addition sugarbeet lines with the resistance, which had been irradiated once or twice and backcrossed for eight generations by Dr. H. Savitsky, were used as maternal parent, pollinator, or both in this study. Portions of those plant materials were irradiated with gamma-rays on the inflorescence at various developmental stages between initiation of floral buds and the beginning of anthesis, with dosages ranging from 700 to 1,900 roentgen for group A plants and 2,000 to 2,800 roentgen for group B.

The rate of nematode resistant transmission was rather low in all occasions. Most of the resistant progeny contained 19 chromosomes, with an average frequency of 10.52% through ovules (Table 1). The probable pollen (with 10 chromosomes) transmitted 19-chromosome resistant progeny was obtained at 0.025% rate. The 19-chromosome pollen parent of this plant was irradiated with gamma-rays 1,000 r at the time of first anthesis.

The irradiated pollen (1,300 r, just prior to anthesis) also resulted in one diploid resistant progeny among the 1,850 plants examined. However, this diploid plant did not grow vigorously. The other two diploid resistant plants were isolated from untreated parents. One of them carried an annual bolting characteristic. Thus the average frequency of identifying nematode resistant diploid sugarbeet from progeny of the resistant 19-chromosome plants was approximately 0.046%, based on the observation of 6,580 plants.

Performance Among the Progenies of a Diploid Nematode Resistant Sugarbeet

The diploid nematode resistant sugarbeet, selection 51501, was recovered from 2,500 plants of self-sterile resistant alien monosomic addition lines that were grown and interpollinated in an isolated field plot in 1975. The rate of nematode resistant transmission was estimated to be 13.3%. The resistant progeny were crossed to diploid nematode susceptible plants to further examine the resistance inheritance. The results in Table 2 showed that the overall nematode resistance transmission rate remained the same as that of the original 51501. However, the transmission frequencies vary from 5.3% to 21.4% based on the moderate numbers of progeny plants screened. Whether the divergence had been caused simply by sample error or other reasons was unknown. It seemed that the pollen transmitted resistance did not bring together a significantly improved genotypical composition, since only 1% increment of transmission rate was demonstrated in the C17/51501 group (Table 2).

Meiotic behavior of selection 51501 was not normal, including the formation of two dicentric bridges at approximately 1.25% frequency in both the first and second meiosis. Whether the structural aberration of those chromosomes had any interrelation with the nematode resistance was not known. Cytological examination of the progeny plants showed that both the resistant and susceptible progenies contained the same category of structurally aberrant chromosomes (Table 3). If nematode resistance was associated with one (or more) rearranged chromosome(s) then the resistant progeny plants should form at least one bridge theoretically, and the susceptible progeny should carry no more than one bridge. In this study, however, one susceptible progeny with two bridges and one resistant plant with no bridge had been observed from the 29 progeny plants investigated (Table 3). Therefore, unless crossing-overs involving the chromosome segments that carried the resistant factor had occurred, the transmission of nematode resistant factor might be actually independent from the bridge formation mechanism(s).

One nematode resistant plant, selection 61202, derived from 51501 was triploid, $2n=27$. This triploid resistant plant was transplanted into an isolation chamber together with one self-sterile, nematode susceptible diploid plant of line C17. Both plants grew vigorously and produced numerous flower branches. Sample microsporocytes of 61202 were collected for cytological examination. The chromosomal distribution of this plant at anaphase I was in close agreement to the theoretical distribution (Table 4). However, there were some 20% of pollen mother cells proceeding abnormal meiotic behavior, which was not the case for the control normal triploid sugarbeets, i.e., less than 2% abnormalities.

Progeny of plant 61202 has been partially investigated. Plants with chromosome numbers of 18, 19, 20, 26, and 27 were found. None of the single chromosome number groups were classifiable as totally nematode resistant. Many seeds failed to germinate, and several seedlings grew abnormally and died at an early stage. If 61202 were derived from a diploid egg and carried two doses of nematode resistant factor, then all the 27-chromosome progeny plants would likely be resistant. The resistance transmission phenomenon observed in this plant might have occurred from one of the following possibilities: a) the original diploid megaspore was developed from a first meiotic division restitution nucleus, b) chromatid segregation, or double reduction, had taken place during meiosis of the megasporocytes, c) a multi-genic controlling system was involved in the production of nematode resistance, or d) a haploid egg of 61202 was fertilized by a diploid pollen grain from the susceptible pollinator.

INTERSPECIFIC HYBRIDIZATION

VULGARIS-PROCUMBENS HYBRIDS

Helen Savitsky

The diploid nematode-resistant plants have well developed foliage, good roots and cannot be distinguished from normal sugarbeets. No characters peculiar to B. procumbens that are caused by deleterious genes of the wild species have been observed in diploid nematode-resistant plants. However, the rate of resistance transmission is not yet sufficient for incorporation into commercial varieties. The inadequate rate of resistance transmission is caused by insufficient association of the B. procumbens segment with the B. vulgaris chromosome in meiosis of nematode resistant plants.

A study of nematode-resistance transmission indicated that resistance is transmitted by female gametes (average transmission 24%) and by male gametes at lower frequency (average transmission 12%). Transmission of resistance by pollen enables the development of homozygous nematode-resistant lines. Obtaining these lines is important because all offspring of homozygous plants will be resistant due to more normal meiosis. The development of resistant varieties will thereby be facilitated.

Work in 1978 was concentrated on the development of homozygous resistant lines and on experiments destined to increase the transmission of cross-overs of the B. vulgaris chromosome bearing the B. procumbens segment. To obtain self-fertile homozygous lines, the nematode-resistant plants were crossed with inbreds. The F_1 resistant plants were selected and selfed. In 32 self-fertile F_2 progenies 1,920 plants are being tested for resistance. The individual F_2 lines differed in the rate of resistance transmission. The occurrence of resistant plants varied from 14 to 41 percent. Several F_2 lines had high transmission rates varying from 29.4 to 41 percent.

To obtain self-sterile homozygous lines the resistant F_3 plants were intercrossed, and the F_4 progenies of 33 F_3 plants were tested for resistance. The number of tested self-sterile F_4 plants was 1,850. Transmission rates of resistance varied in the individual F_4 populations from 10 to 40 percent. The number of resistant plants was high in some F_4 populations, reaching 36.4 and 40 percent. In F_1 hybrids derived from hybridization of nematode-resistant and nematode-susceptible plants only rare plants transmitted resistance at the 27-30 percent rate.

A considerable increase in the percent resistant plants in the progenies of self-fertile and self-sterile hybrids derived from mutual transmission by female and male gametes indicates that such material should be used for development of homozygous plants. Self-sterile and self-fertile lines with the highest transmission rates were selected to increase the transmission of nematode resistance and for the development of homozygous nematode-resistant lines in succeeding generations.

To facilitate the transmission of the B. vulgaris chromosome bearing the B. procumbens segment the 22 self-fertile and 24 self-sterile nematode-resistant plants were irradiated at the Lawrence Irradiation Laboratory of the University of California to decrease the size of B. procumbens segment. Their progenies will be tested for resistance. To increase transmission of resistance by pollen, 1,630 plants obtained from pollen transmission during two generations were tested for resistance. A few plants with pollen transmission reaching 19 and 22 percent were selected. The cytological study of diploid nematode-resistant hybrids included the study of meiosis and the determination of chromosome numbers in selected plants.

VULGARIS-COROLLIFLORA HYBRIDS

Because of the very low transmission of curly top resistance in hybrids described in previous reports the following methods were applied. Repeated selections for curly top resistance were made in the old hybrids possessing 27 chromosomes. Ten highly resistant plants were selected in the progenies of these plants after inoculation with a virulent strain of curly top virus. In order to obtain hybrids in which curly top resistance is derived only from B. corolliflora, the tetraploid plants of the highly curly-top susceptible sugarbeet line 742 are being produced for use in hybridization with B. corolliflora. This work is conducted in cooperation with Dr. McFarlane.

Field Evaluation of Root Toughness in Sugarbeet

I. O. Skoyen and R. T. Lewellen

The 1978 field studies on root toughness (fiber content of roots) were similar to the preliminary study reported in 1977 ("Sugarbeet Research" - 1977 Report, pages A77-A80). The evaluation of environmental effects on root toughness was emphasized in two 1978 tests seeded at different dates and root selections for both high and low fiber content in a third test were emphasized.

Materials and Methods--Two tests, each with the same 24 entries, were seeded November 16, 1977 and February 1, 1978, respectively. The tests included representative multigerm and monogerm inbred lines, F₁ hybrids, open-pollinated lines, and hybrid varieties developed at the U.S. Agricultural Research Station, Salinas, California. A third test of 12 entries was seeded May 2, 1978. Root toughness was measured on a single plant basis as lbs. pressure required for a blade to penetrate a root 2.54 cm deep. Measurements were made in half pound increments. Root probes were made 1 to 2 inches below the crown and horizontally to the vertical plane of the roots.

The modified Magness-Taylor pressure tester used in 1977 was replaced with an Effegi penetrometer in 1978. The same blade used in 1977 toughness measurements was used for tests 1 and 2 in 1978. Dimensions of the blade were 1 x 15.75 mm (15.75 mm cross section) x 2.54 cm long. For test 3, the blade used measured 1 mm x 1 cm (10 sq mm cross section) x 2.54 cm long. The dial of the Effegi penetrometer has a graduated dial capacity of 27 foot lbs. pressure but it can be readily interpreted up to 28 foot lbs. The 28 lb. toughness measurement has been included in the test results.

Results and Discussion--As was demonstrated in 1977, the mean root toughness among the different types of lines represented in the tests in 1978 appeared to occur at random (Tables 1 and 2). Inbred lines and F₁ hybrids tended to have higher mean root toughness than open-pollinated lines and 3-way hybrids (Table 1).

Arranging toughness measurements into frequency classes showed that a broad range of toughness (apparent root fiber content) within lines also occurred in 1978 (Tables 1 and 2). The pounds pressure required for the blade to penetrate the roots were also higher in 1978. Combining the 12- to 22-lb. pressure frequency classes showed that this portion of the distribution accounted for 57% of the roots for the "softest" variety and as low as 11% for the toughest (Table 1). These values were 30% lower than those for 1977. This reduction was probably due to: (1) the Magness-Taylor probe underestimated root toughness (it was more difficult to keep in calibration than the Effegi) and (2) beets were tougher in 1978 than in 1977.

In test 3, root toughness comparisons were made between five topcross pollinators and their 3-way hybrids (Table 2). The mean probe values show that there were toughness differences between hybrid and pollinator only for Y601 and Y740 with the hybrid having the toughest roots in both instances. Both the late seeding date and the narrower probe blade used for test 3

probably contributed to the lower root toughness values compared with those of tests 1 and 2. Selections for both high and low fiber content based on probe values were made in test 3. Progeny of the selections will be evaluated to determine the potential for change in root toughness in sugarbeet populations.

So far the sugarbeet populations tested for root toughness (root fiber content) have all had a number of roots that the probe penetrated only at pressures beyond the scale of the probe or were not penetrated at all. More of these "extra tough" roots were generally found as test plants increased in age. The mean percentage of plants with roots requiring over 28 lbs. pressure for penetration was 16.3 in test 1 compared with 8.1% for the later seeded test 2 (Table 1). The toughest variety in test 1 was US H9A with 41% of the plants measuring over 28 lbs. pressure for probe penetration. The most important result to be gained from selection for softer (less fibrous) roots could be the reduction of the proportion of "extra tough" roots, particularly in "tough beet years."

No specific measurements of environmental effects were made in 1978, however, observations of climatic and soil influences were possible between tests 1, 2 and 3. The higher mean toughness of roots in test 2 compared to that of test 1 probably occurred as a result of soil and climate conditions that existed during and for several weeks following seeding. Test 2 was included in test seedings made during a brief interruption in a rainy period. The seedings were made January 31 - February 1 in soil still too wet from rain, followed by several weeks of intermittent rain which kept the soil completely saturated. The result was that, throughout the growing season, test 2 and its companion tests never grew as well or appeared to be as thrifty as either test 1 seeded earlier or test 3 seeded later. Test 1 and test 3 were seeded under conditions nearly optimum for our area.

Field evaluation of environment vs. root toughness will require additional testing to evaluate year and seasonal variation.

I. EXPERIMENTAL FIELD TRIALS

A. Agronomic Data

Soil Types: North Farm - silty loam
Farmington Farm - sandy loam

Fertilizer: 950 lbs/acre of 16-20-0

Planting Dates: North Farm - May 12
Farmington Farm - May 5

Thinning Dates: North Farm - June 20 - 23
Farmington Farm - June 12 - 15

Irrigations: Sprinkler irrigated at both farms until two weeks prior to harvest.

Harvest Dates: North Farm - October 10 - 12
Farmington Farm - October 18 - 19

Harvesting Procedures: Tops were removed by beating twice with a roto-beater then topped and dug with a two-row harvester. Beets/plot were counted as they went into a weighing basket on the harvester. Two 10-beet samples were taken at random from each 2-row plot for sugar analysis. All beets in each plot were weighed to determine root yield.

COMMERCIAL AND EXPERIMENTAL VARIETY TEST

J. C. Theurer and D. L. Doney

Nine of the current major commercial hybrid varieties developed in the United States and several experimental varieties were grown at Logan and Farmington, Utah, in 1978. Each entry was planted in six replicates of 2-row plots, 36 feet long with plants thinned approximately 1 foot apart in the row. The Farmington plots had excellent stand--a small amount of curly top and some powdery mildew. The test at Logan had fairly poor stands and severe curly top infection. The Nortron treatment for weed control had a detrimental effect and was probably the major problem in stand reduction at Logan. Sugar percentage, root weight, and quality factors for these varieties are listed in tables 1 and 2.

GWD2 had significantly the greatest yield at Farmington, and UI8 was highest in yield at Logan. An experimental variety, dl48, was not significantly different in yield compared to GWD2 at Farmington, but this variety was extremely high in potassium and had the greatest impurity index in the test at this location.

The experimental variety, 46F3 having L19 parentage, and variety ACH14 had the highest sucrose percentage in the test. Stand differences at Logan and the degree of curly top susceptibility greatly influenced the yield of experimental varieties that lacked resistance to curly top.

Table 1. Root yield, sugar percentage, and quality factors for commercial and experimental hybrids at Farmington, UT. 1978.

II. SELECTION METHODS

D. L. Doney and J. C. Theurer

Sugarbeets are very sensitive to environmental influences and interact with the varying environmental factors. High interactions are especially noted for root yield and environment (genotype x environment).

In space-planted nurseries (to eliminate competition effect), the majority of the variation in root size is due to environmental effects. Selection in these nurseries generally result in environmental deviates and not genetic deviates. Some exceptions to this are when a severe selection pressure is exerted on the plant population such as disease or insects. However, selection for yield on an individual plant basis has not been successful because of the large environmental interactions.

Progeny testing has been a more reliable method for selection for root yield. However, this requires a large outlay in land, time, equipment, and labor.

Over the past several years, we have been investigating alternate methods of selection in an attempt to develop a more reliable, more precise, and more efficient selection procedure. In this section, we will report on several of these selection methods.

HYPOCOTYL DIAMETER AND SPECIFIC GRAVITY

Devon L. Doney

In the past, we have reported on the hypocotyl diameter and specific gravity techniques separately. The hypocotyl diameter (HD) technique was developed for root yield without any regard to percent sugar, whereas the specific gravity (SG) is a test for percent sugar without any regard to root yield.

These two selection methods tend to have inverse relationship; i.e., selection for large HD gives an increase in root yield and a decrease in percent sugar, while selection for SG gives an increase in percent sugar and a decrease in root yield.

In this experiment, we selected for both parameters in the same population. For specific gravity, we divided the population into three groups - SG1 (high SG), SG2 (medium SG), and SG3 (low SG). Likewise the population was divided into three groups for HD (high, medium, and low). Selected plants were allowed to interpollinate in their respective groups and seed harvested for groups: SG1, SG2, SG3, high HD, medium HD, and low HD. Plants with both SG1 and high HD were few in number and produced insufficient seed for testing.

These six selection populations were tested in the field along with the original parent population and check varieties; GWD2, UI8, AH10, and US22/3 (Table 1). The results tend to confirm our earlier findings. The SG3 population (h534) gave the lowest percent sugar, and the low HD population (h545) gave the highest percent sugar (Table 1). The root yield for the HD selections was high > medium > low. One deviation that was not expected was the SG1 population, (h532), which gave a medium percent sugar and a high root yield. We expected a high percent sugar and low yield. Its yield and gross

sugar were significantly greater than the commercial check hybrids. This selection needs further testing to verify its superior performance. The parent (f354) was close to the test mean for all measured characters.

Table 1. Percent sugar, root yield, gross sugar, and impurities for parent - Selections for HD, selections for SG, and check hybrids.

| Code | Description | % Sugar | Ton/AC | Lbs/AC | N | Na | K | Index | Rt. No. |
|------|-----------------|------------|--------|--------|-------|-------|--------|-------|------------|
| h532 | SGI of f354 | 15.2 | 23.24 | 7013 | 531 | 354 | 1695 | 715 | 68.2 |
| h544 | High HD of f354 | 15.6 | 21.85 | 6834 | 500 | 234 | 1454 | 607 | 62.7 |
| GWD2 | GWD2 | 15.6 | 19.35 | 6210 | 558 | 166 | 1379 | 620 | 69.5 |
| UI8 | UI8 | 15.5 | 19.89 | 6175 | 502 | 249 | 1280 | 588 | 69.0 |
| AH10 | AH10 | 15.2 | 20.11 | 6174 | 542 | 219 | 1572 | 668 | 54.3 |
| f354 | Parent | 15.6 | 19.53 | 6103 | 478 | 285 | 1458 | 606 | 62.3 |
| h542 | Med. HD of f354 | 15.4 | 19.79 | 6084 | 391 | 289 | 1423 | 551 | 59.5 |
| h533 | SG2 of f354 | 15.4 | 19.18 | 5893 | 605 | 321 | 1652 | 734 | 57.7 |
| h545 | Low HD of f354 | 16.0 | 18.34 | 5861 | 375 | 245 | 1458 | 518 | 58.8 |
| h534 | SG3 of f354 | 14.9 | 19.57 | 5795 | 530 | 409 | 1523 | 710 | 53.8 |
| F | | 2.62 | 2.76 | 2.67 | 5.00 | 13.37 | 4.08 | 8.35 | 2.15 |
| LSD | | 0.51 | 2.98 | 936.7 | 83.4 | 48.5 | 163.3 | 65.8 | 10.8 |
| CV | | 2.9 | 13.3 | 13.6 | 14.60 | 15.51 | 9.64 | 9.10 | 15.77 |
| Mean | | 15.4 | 19.4 | 5964 | 510.8 | 276.2 | 1496.6 | 639.3 | 60.61 |

This test points out the need to combine both of these selection methods into a selection index. Since it is easier to test for SG than HD, a practical approach would be to discard all beets below a set SG and test only those beets above the set GS for HD. This can be easily accomplished by 1) preparing a tank or barrel of salt (NaCL) solution of the desired SG, 2) dumping all beet roots into the solution, and 3) saving only those that sink. The saved roots can then be tested for HD by our published method. This system would allow the breeder to select in large populations with a minimum amount of time and effort.

SEEDLING SELECTION

D. L. Doney

Over the past few years, we have investigated several seedling selection methods. One method that has proven successful is the hypocotyl diameter of 3-week-old seedlings.

The hypocotyl diameter selection technique has been tested over a wide range of genotypes and in several breeding methods. In most cases, it has proven successful in improving root yield but results in a decrease in sugar percentage. This past year we have been investigating methods of including selection for sugar percentage in the seedling stage in connection with the hypocotyl diameter selection.

Since our studies of osmotic potential in the seedling stage indicated that this criterion would be effective only on L19 type germplasm, we have taken an alternate selection approach and developed the following hypothesis:

Facts:

- (1) Plants largest in diameter at 3-weeks grow most rapidly and are largest in root yield at harvest time.
- (2) Small celled plants have the highest sugar percentage.
- (3) Small celled plants have highest percent dry weight because of more cell wall per unit volume.

Therefore:

- (1) Percent dry weight in the seedling stage will give a relative measure of sugar percentage potential and
- (2) Total dry matter per unit time will give a relative measure of total sugar production potential.

We have adapted an agar cutter for cutting 3mm sections from the hypocotyl of 3-week-old seedlings. Measurements made on these 3mm sections are diameter, percent dry weight, and total dry weight. From these data, the following assumptions are made:

| | | |
|------------------|---|-----------------------|
| Root diameter | = | root yield potential |
| % dry weight | = | % sugar potential |
| Total dry weight | = | total sugar potential |

From a test involving 20 hybrids varying in yield and percent sugar, significant correlations of 0.65, 0.69, and 0.60 were obtained for the above relationships, respectively.

In another test, 13 hybrids were divided, using the above relationships, into high, medium, and low for percent sugar, root yield, and total sugar (Table 5).

Table 5. Classification of hybrids into high, medium, and low classes for % sugar, root yield, and gross sugar based on the percent dry matter, root diameter, and total dry matter of 3mm root sections of 3-week-old seedlings.

| <u>% Sugar</u> | | |
|----------------|------------------|-------------------------|
| <u>High</u> | <u>Medium</u> | <u>Low</u> |
| L19 | AH12 | Beta 1345 |
| ACH-14 | Mono-Hy-E4 | GWD2 |
| L53xL19 | UI-HS-Hybrid | Hilleshog Broadbase "Z" |
| Mono-Hy-Z1 | Hilleshog Vytomo | (EL30x030)xL10 |
| | L9xL19 | |

| <u>Root Yield</u> | | |
|-------------------|-------------------------|------------|
| <u>High</u> | <u>Medium</u> | <u>Low</u> |
| AH12 | (EL30x030)xL10 | ACH-14 |
| GWD2 | Beta 1345 | L19 |
| Mono-Hy-Z1 | UI-HS-Hybrid | L53xL19 |
| L9xL19 | Hilleshog Vytomo | Mono-Hy-E4 |
| | Hilleshog Broadbase "Z" | |

| <u>Gross Sugar</u> | | |
|--------------------|------------------|-------------------------|
| <u>High</u> | <u>Medium</u> | <u>Low</u> |
| GWD2 | ACH-14 | Mono-Hy-E4 |
| AH12 | Beta 1345 | Hilleshog Broadbase "Z" |
| L9xL19 | L53xL19 | (EL30x030)xL10 |
| Mono-Hy-Z1 | Hilleshog Vytomo | L19 |
| | UI-HS-Hybrid | |

These criteria placed most of the hybrids in the right class (high, medium, or low); however, some hybrids were misclassified. This classification may be improved with better control of environmental variation.

We have made selections in a heterozygous population for different combinations of the above relationships. These selections will go through a generation for seed increase and tested in the field for effects of the different types of selection pressure.

RECIPROCAL RECURRENT SELECTION

D. L. Doney and J. C. Theurer

The reciprocal recurrent selection breeding method (RRS) has been adapted to sugarbeet and published in Field Crops Research 1 (1978) 173-181 (a new international journal published by the Elsevier Scientific Publishing Company, Amsterdam, The Netherlands).

This past year was the fourth year of the first cycle of RRS. Seed produced from crossing blocks of the two populations in 1977 was tested in replicated field trials. Of the 33 lines in Population A, 21 produced sufficient seed for field testing. However, only 11 of the 33 lines in Population B produced enough seed to test in replicated field trials. It should be noted that the seed produced in Population A resulted from each Population A line crossed to a random sample of all lines in Population B and vice versa for seed produced in Population B. Therefore, these trials were to test the combining ability of lines in Population A with Population B and lines in Population B with Population A.

Table 2. Percent sugar, root yield, gross sugar and impurity factors for combining ability of lines in Population A to Population B.

| Code | No. | % Sugar | Rt. Wt. Ton/AC | G.R. Sugar Lbs/Ac | N ppm | Na ppm | K ppm | Index | Root Number |

The results of these field trials are given in Table 2 for Population A and Table 3 for Population B. Significant differences between lines (differences in combining ability) were noted for all measured characters (tables 2 and 3). In both populations, there were lines equal to or better than the commercial hybrids in percent sugar, root yield, and gross sugar. It appears that there are sufficient superior genes in this material to make progress in subsequent selection cycles.

Although there was insufficient seed to test all lines in replicated field trials, there was sufficient seed to test all lines in the hypocotyl diameter test in the greenhouse. All lines were tested for hypocotyl diameter at three weeks of age. In addition, a 3mm section was taken from each root, and the total and percent dry matter were determined. This method will be discussed in more detail in the following section.

These data for both population lines are presented in Table 4 as deviations from the mean. From these data, lines were selected for high HD, high total DM, high percent DM, and combinations of these parameters.

The selection cycle schedule was to plant stecklings of the selfed seed of the selected lines for a polycross next year. However, due to a misunderstanding, the seed was not planted. This will set our program back a year; i.e., selfed seed of the selections will be planted in 1979 and the "polycross of best lines" completed in 1980.

COMPARISON OF HIGH AND LOW HYPOCOTYL DIAMETER
AND ROOT/LEAF RATIO SELECTIONS

J. C. Theurer and D. L. Doney

Two seedling selection methods have been suggested for rapid and efficient improvement of sugarbeet yield. One method is based on the measurement of the hypocotyl diameter of seedlings grown in sand benches in the greenhouse for 21 days (1). Selection by a second method is based on the ratio of tap root fresh weight:leaf blade (laminae) fresh weight for 21-day-old seedlings grown in a growth chamber (2), hereafter called R/L ratio method.

In 1977, high and low hypocotyl diameter selections were made from the heterogeneous population 6F3 in accord with the standard published (1) technique. After photothermal induction of selected seedlings, they were grouped by high and low plants in greenhouse isolators for seed increase. Selection was made for R/L ratio in the same population by a modification of the technique suggested by Snyder and Carlson (2). Plants were seeded in 6-inch pots in a sand bench in the greenhouse. The day after emergence they were thinned to a single plant per pot, and thereafter each pot was irrigated daily with an equal volume of complete nutrient solution. Plants were continually illuminated with a bank of gro-lux lights 24 inches above the bench. The plants were rotated to a different site in the sand bench every four days to more uniformly control environmental influences. Plants were harvested after 35 days growth which was about the same stage of plant development that Snyder used when selection was made in a growth chamber (personal communication). Tap root fresh weight and laminae weight were obtained on each plant. The highest 10% R/L ratio plants and the lowest 10% R/L ratio plants were selected for seed increase in isolation units.

In 1978, a field comparison was made of the four mass selections and the parent population. Because seed was limited for the selections, they were first seeded into Japanese paper pots, then transplanted to the field. Each field plot consisted of two rows 36 feet long with plants 1 foot apart in the row. Six replicates of the five entries were studied. Non-competitive beets were eliminated from the plot at harvest, then the root weight, top weight, and sucrose percentage were determined.

RESULTS

Early in the growing season, mid-June, the high R/L ratio plants showed greater vigor and more top growth than the other selections, or parent population. By the latter part of August, this difference in top growth was no longer apparent. The Low Hypocotyl Diameter Selection showed considerable variability in top growth of individual plants at harvest. This variability also has been noted for Low H.D. selections in other populations. The top growth of other entries was relatively uniform.

The root weight, top weight, and sucrose percentage for the selections and parent are shown in Table 1. The High R/L Ratio, Low R/L Ratio, and High H.D. selections had a greater mean weight per beet than the parent. Low H.D. had lower root weight than the parent. However, none of the root weights differences were significant. The Low HD Selection had significantly more top

Table 1. Comparative root weight, top weight, sucrose percentage and gross sugar for seedling selection methods.

| Selection | Gross Sugar T/AC | Root Weight g/Beet) | Top Weight g/Beet | % Sucrose |
|----------------|------------------------|---------------------------|-------------------------|--------------|
| High R/L Ratio | 25.2 | 961 | 841 | 15.3 |
| Low " " | 25.1 | 957 | 832 | 14.6 |
| High H.D. | 24.9 | 952 | 828 | 14.9 |
| Low " | 22.0 | 839 | 1008 | 14.8 |
| Parent | 23.9 | 926 | 863 | 14.4 |
| Mean | 24.2 | 927 | 874 | 14.8 |
| LSD 0.05 | 3.1 | 50 | 77 | 0.8 |
| C.V. | 4.94 | 4.60 | 7.46 | 4.30 |

weight than the parent and the three other selections. The High R/L Ratio Selection had significantly higher sucrose percentage than the parent population. This may have been a chance occurrence, however, since selection for Low R/L Ratio was ineffective.

Evaluations of H.D. and L/R Ratio Selection will be continued for the next few years, using both mass and recurrent selection methods.

III. PHYSIOLOGICAL GENETICS

SEEDLING PHYSIOLOGY

D. L. Doney

There has been much discussion and research in recent years concerning the development of physiological selection criteria (selection based on principle metabolic functions). A critical fundamental necessary for the development of physiological selection criteria is a knowledge of the basic physiology. In particular, if we are going to be able to develop effective selection criteria in the seedling stage, we must know the basic development, growth parameters, and physiology of the sugarbeet seedling. In this section I will report a summary of our seedling physiology studies.

1. Germination - The first plant part emerging from the seed is the radical. It is generally 2-3cm in length and is made up of 8 to 10 rows of cortex cells with a center core of meristematic tissue (very small cells). The number of cortex cells is relatively consistent with only a slight variation in number between widely divergent genotypes. However, there is a large difference in cell size between genotypes. The cell size of cortex cells correlates with the genetic cell size potential of a particular genotype. These cells do not divide but increase in size as the center meristematic cells divide and grow. These cells grow and stretch and are eventually sloughed off when the plant is about 3 weeks old. The splitting of the root at this stage is the sloughing off of these cells.

2. True Root - The true root develops from the growing center core. A primary cambium is first initiated when the plant is about 10 to 15 days old. The remaining cambial regions (rings) are developed very rapidly from this primary cambium outward. By the time the plant is 30 to 35 days old (root 2-3cm in diameter), all the cambium rings are complete. Vascular bundles (xylem and phloem) are formed around the cambial layers. Storage parenchyma cells separate the cambial layers. By the time the root is 2-3cm in diameter, root differentiation is complete. From then on, growth is by cell enlargement and cell division taking place at the same time. The hypocotyl (root portion above soil level) becomes indistinguishable from the tap root as the root matures. The cambial rings are difficult to follow in the crown where the vascular bundles tend to converge to the vascular bundles coming from the petioles.

3. Leaves - The emerging cotyledons carry on photosynthesis until about the four-to-six-leaf stage when they senesce and drop off. The first true leaves emerge at about 10 to 15 days after germination. Leaves emerge in pairs and are initiated at about two to four per week throughout the growing season. In the early stages of growth, the leaves grow more rapidly than the root, but, as the root becomes more dominant, it demands more photosynthate and grows more rapidly.

4. Growth Curves - Seedling growth will be illustrated by growth curves of three divergent genotypes: 1) Blanca (high yield, low sugar); 2) GWD2 (high yield, medium sugar); 3) L19 (low yield, high sugar). The fresh weight curves for top and root are shown in figures 1 and 2. The rate of growth is very slow until the plants are about 15 to 20 days old.

After this point, the rate of growth for both tops and roots increases very rapidly. This increase corresponds with the development of the first true leaves. Differences between genotypes were evident at a very young age. The rate of increase in root-fresh weight is faster than that for leaves after about 25 days. This is reflected in the change in root/shoot ratio (Figure 8). The dry weight growth curves were similar to the fresh weight curves (figures 3 and 4), except the genotype L19 began increasing in dry weight (faster than Blanca), in both the root and top at about 30 days. This change reflects the higher percent dry weight of the L19 genotype (figures 5 and 6). Percent dry weight increased with time for all three genotypes in both roots and tops (figures 5 and 6). Significant differences between genotypes could be detected for percent dry weight as early as 15 days of age. Differences in root diameter were also detectable at a very young age (Figure 7). An important fact about most of the growth curves is that the genetic differences are established very early and those relative differences remain throughout the remainder of the growing season.

Another important curve is the root/shoot ratio (Figure 8). The ratio decreases up to about 25 days of age. This is because the leaves are growing more rapidly than the roots. At between 20 and 30 days of age, the ratio changes and begins increasing. This happens for all genotypes and is graphed for such divergent genotypes as GWD2 and L19 (Figure 8). The change in this curve reflects the shift in root growth. Although the root is still much smaller than the top, it is growing at a faster rate. This continues throughout the growing season, and the root eventually exceeds the top weight. The point of inflection (change in direction) of this curve corresponds to the stage of root differentiation at which time all cambial rings are formed. At this point more meristematic tissue is available in the root to demand photosynthate. The plant responds by sending a higher portion of the available photosynthate to the root. It is at this stage that the sink strength of the root becomes dominant rather than later on when the root exceeds the top in weight. This suggests that the shift in photosynthate partitioning is due to photosynthate demand rather than hormonal.

The relative relationship of this ratio between genotypes is established at a very early age, although the curve changes in direction with time. This relationship is evident throughout the growing season as shown in Table 1. Two genotypes (L19 and L10), differing greatly for root/shoot ratio, had the same ratio relationship from the first of July to the middle of September (Table 1).

Table 1. Root/shoot ratio for L19 and L10 from July 1 to September 8.

| | Rt/Shoot Ratio | | L19 as % of L10 |
|-------------|----------------|-------|--------------------|
| | L19 | L10 | |
| July 1 | .158 | .241 | 66% |
| July 28 | .419 | .661 | 64% |
| August 18 | .692 | 1.125 | 62% |
| September 8 | .890 | 1.364 | 65% |

PHYSIOLOGY OF SUGAR PRODUCTION

D. L. Doney

When we select for total sugar production, we are selecting at the endpoint of a number of complex biochemical, physiological, and developmental processes. Each one of these complex processes interacts with each other and with other environmental influences. The effect of these interactions is an increase in variation at the endpoint of selection over any one of the components or combination of component processes. For this reason, selection for genetic differences at the endpoint is very difficult and generally results in differences due to environment rather than genetic.

Many attempts have been made at selecting on less complex processes as an alternate trait. However, much of this effort has been a random testing of procedures rather than a systematic approach and has been unsuccessful. We feel that a systematic approach will be much more productive; i.e., identifying limiting processes at each subsequent lower level of complexity. Sugar production can initially be reduced to root yield and sucrose percentage. In this section, I will report on the next lower level of complexity:

1. Root Growth - After ring differentiation is completed (when the root is about 2-3cm in diameter), root growth is by cell division and cell enlargement taking place at the same time. Genetic differences in root size are determined by genetic differences in cell size and genetic differences in cell division rate. An example is given in Table 2 of these genetic differences and how cell size and cell division rate interact. Blanca is a low sugar mangle, and L19 is a high sugar line. Data are for true root tissue of young plants (15 to 30 days of age); however, genetic differences are already established. At 15 days there is no difference in cell size, but by 30 days the cells of Blanca are twice the size of L19. L19 has less true root cells at 15 days than Blanca; however, it has a faster cell division rate than Blanca, and by 30 days it has almost twice as many cells as Blanca. Thus, the genotype with small cells compensates by producing more cells. This gives them

Table 2. Cell size, cell number, and surface area for Blanca and L19 from 15 to 30 days after planting. Measurements are for true root cells only.

| Line | Age (days) | Cell Diameter | Cell Size | Surface Area/ Cell | 3mm Section | | | |
|--------|---------------|------------------|------------------|--------------------------|---------------|--------------------------|-------------------------------|-----------|
| | | | | | Volume | Total Surface Area | Surface Area per Volume | Cells |
| | | cm | $\times 10^{-9}$ | $\times 10^{-6}$ | cm^3 | cm^2 | cm^2/cm^3 | |
| Blanca | 15 | .00107 | 0.65 | 3.60 | .000106 | 0.59 | 5540 | 163,897 |
| | 20 | .00120 | 0.92 | 4.60 | .000401 | 2.00 | 4997 | 435,583 |
| | 25 | .00132 | 1.19 | 5.39 | .000951 | 4.31 | 4528 | 798,990 |
| | 30 | .00141 | 1.47 | 6.33 | .001846 | 7.95 | 4307 | 1,256,082 |
| L19 | 15 | .00107 | 0.64 | 3.60 | .000525 | 0.30 | 5625 | 82,032 |
| | 20 | .00108 | 0.67 | 3.66 | .000338 | 1.85 | 5470 | 505,155 |
| | 25 | .00110 | 0.70 | 3.80 | .000887 | 4.81 | 5426 | 1,266,566 |
| | 30 | .00112 | 0.73 | 3.94 | .001715 | 9.26 | 5399 | 2,349,905 |

almost the same volume at 30 days. A cubic cm of small cells will have more surface area (cell wall) than a cubic cm of large cells. Therefore, the small-celled genotype L19 has more surface area (12%) than the large-celled genotype (Blanca), although it is about 7 percent smaller in volume. More photosynthate is being partitioned per unit volume to cell wall in L19 than in Blanca. Consequently, L19 has a higher percent dry weight than Blanca.

2. Percent Sugar - Last year, we reported on the relationship of osmotic potential and sugar percentage potential. Since only L19 high-sugar germ-plasm could be detected in the seedling stage by osmotic pressure, we have investigated other parameters influencing sugar percentage.

One parameter that seems to be consistent in all the material we have studied is the relationship of percent sugar to cell size. Small-celled genotypes have high-sugar percentage, and large-celled genotypes have low-sugar percentage. This is consistent with other workers also.

This relationship was also present in our hypocotyl diameter studies. One of the problems with our hypocotyl selection populations was that it was accompanied with a decrease in sugar percentage even though we were able to increase root yield. Cellular level studies of our hypocotyl diameter selections revealed that the selections were larger because the cells were larger (Table 3). In all three tests studied, the selections with large hypocotyl diameter had larger cells (Table 3). Cortex cells (initial cells laid down by the germinating seed) were also larger for the large hypocotyl diameter selections (Table 4). An inverse relationship between sugar percentage and cortex cell size was present in this material (Table 4).

Table 3. Hypocotyl diameter and mean cell size of 3-week-old seedlings for large and small hypocotyl diameter selections.

|---|-------------------------------------|----------------|
| | <u>Cell Volume</u> cm^3 | <u>% Sugar</u> |
| Large HD Selection | 9.4×10^{-8} | 14.5 |
| Small HD " | 6.2×10^{-8} | 15.4 |

In a study involving Blanca (a low-sugar line) and L19 (a high-sugar line), a direct relationship between sugar percentage and cell wall per unit area was observed. These two genotypes differed 9-fold in mean cell size; i.e., Blanca had cells nine times larger than L19. However, the cell wall (surface area per cubic cm) of L19 was almost twice as great as that for Blanca. The sugar percentages were 9.5 and 18.0 for Blanca and L19, respectively. Thus, the difference between Blanca and L19 in cell wall per unit area was about the same as the difference between these two genotypes in sugar percentage. We have observed this relationship in other genotypes.

3. Yield - % Sugar Relationship - These effects and relationship at the cellular level are diagrammed in a simple form in Figure 9. Root yield is influenced by both cell size and cell division rate; whereas, sugar percentage is determined largely by cell size and, to a lesser degree, by osmotic potential. This implies that genes that increase yield by increasing cell size are the same genes that affect sugar percentage. If we increase yield by increasing cell size, we will decrease sugar percentage. However, if we increase yield by increasing cell division rate, we will not affect sugar percentage.

Figure 9. Cellular level components of percent sugar and root yield.

The way these parameters (cell size, cell number, and surface area per unit area) interact with each other is demonstrated in Table 5. These data are presented in relative measurements to demonstrate these relationships but are obtained from actual data. Blanca has a much larger cell than L19 but has a slower cell division rate. When these two factors are multiplied together to obtain a relative size, it corresponds very closely to the relative root yields obtained from actual field trials (Table 5). The relative surface area per

Table 5. Relative cell size, cell division rate, surface area per volume, total surface area, and root yield and gross sugar for Blanca, and L19. Relative cell size and cell division rate were determined from 3-week-old seedlings. Root yield and gross sugar were from a field trial.

| | Relative Cell Size _{1/} Diameter | Relative Rate of Cell Division Diameter | Relative Size Diameter | Root Yield Tons/ha | Relative Surface _{2/} Area/cm ² | Relative Total Surface _{2/} Area/cm ² | Gross Sugar Tons/ ha |
|--------|---|---|------------------------------|--------------------------|---|--|-------------------------------|
| Blanca | 11.34 | 3.97/day | 45.0 | 45.0 | 1.00 | 4.05 | 4.05 |
| L19 | 5.43 | 5.76/day | 31.2 | 29.1 | 1.95 | 5.49 | 5.24 |

_{1/} $\frac{1}{\text{cm}^2} \times \text{constant}$

_{2/} Relative cell size x division rate x surface area/cm² ÷ 11.08

unit area for L19 is about twice that for Blanca and corresponds to their relative sugar percentages. When the relative surface area is multiplied by the relative size, a figure is obtained for the relative total surface area (cell wall area) which corresponds to the total gross sugar obtained from field trials (Table 5).

HORMONE EFFECTS AT THE CELLULAR LEVEL

D. L. Doney

Our research over the past few years has brought out the importance of cell and cell division rate in sugar production. Both of these factors can be manipulated, or changed, genetically. However, changing both in the right direction (small cell size and rapid cell division) is difficult genetically because of compensating effects in photosynthate partitioning. In the physiology of the plant, it seems reasonable to assume that hormones are the key compound conditioning these two parameters, both genetically and environmentally. This past year we have been investigating the effects of a number of hormones on cell size and cell division. Of particular interest are those hormones that affect cell division. In this report, I will report on studies with 2,4-D (2,4, Dichlorophenoxyacetic acid), IAA (Indoleacetic acid), Dow Co 290 (3,6-Dichloropicolinic acid), and Kinetin (6-Benzyl-amino purine).

1. 2,4-D - Several tests were conducted with 2,4-D. Treatments were applied as a spray to the leaves at the two-to-four-leaf stage. Plants were harvested and measurements taken two weeks after treatment. Treatments of greater than 1 ppm were harmful to the plants. This corresponds to about one two-hundredths (1/200) of an ounce per acre. At harvest time, root sections were made and stained for cell size measurements.

In a comparison between concentrations of 0.1 ppm to 10 ppm (Table 8), the 10 ppm had a detrimental effect on the plants. This treatment caused an elongation and twisting of the petiole and a proliferation of root hairs. Few usual effects were observed for the 0.1 ppm and 1 ppm treatments. Data (Table 8) indicate the 0.1 ppm treatment had little effect on the measurements taken. The 1 ppm treatment gave a decrease in top yield and an increase in root yield (Table 8). This increase was largely due to an increase in cell number.

An observation was made indicating that the desired effect was short-lived. The following tests were conducted to evaluate this observation. In these tests (tables 9 and 10), plants were sprayed with 1 ppm 2,4-D at varying intervals. The results of these tests (tables 9 and 10) were less conclusive but did indicate that the effect of 2,4-D on increasing cell division was short-lived (compare the 14 + 21 days treatment with the 14 day treatment).

Table 8. Root and leaf weights, dry weight, hypocotyl diameter (HD), cell size and cell number of 26-day-old plants for differing treatment of 2,4-D.

| Treatment | Leaves | | | Roots | | | Root/shoot | | | Cell Size x10 ⁻⁹ | Cells/ Radius |
|------------|--------|------|------|-------|-------|------|------------|------|-------|--------------------------------|------------------|

| 21,23,25 | | | | | | | | | |
| LSD (0.05) | 0.31 | -- | 0.9 | 0.08 | -- | 1.3 | 15.4 | 0.29 | 14.4 |

Note: Cell size and cell number were determined microscopically from cross sections.

Table 10. Root and leaf weights, dry weights, hypocotyl diameter (HD), cell size, and cell number of 21-day-old plants for treatments of 2,4-D at 1 ppm and repeat applications.

| Date of Treatment (days after planted) | Leaves | | | Roots | | | HD | Cell Size $\times 10^{-9}$ | Cells/ Radius |
|---|--------|-------|------|-------|-------|------|-------|-------------------------------|------------------|
| | Fresh | Dry | % | Fresh | Dry | % | | | |
| | Wt. | Wt. | D.W. | Wt. | Wt. | D.W. | | | |
| | g | g | | g | g | | | | |
| None | 1.91 | 0.193 | 10.1 | 0.28 | .0406 | 14.5 | 124.2 | 1.77 | 82.5 |
| 14 | 1.86 | 0.206 | 11.1 | 0.29 | .0447 | 15.4 | 142.5 | 1.57 | 91.4 |
| 14,16, and 18 | 1.78 | 0.180 | 10.1 | 0.32 | .0442 | 13.8 | 137.7 | 1.63 | 88.1 |
| LSD (0.05) | 0.30 | -- | NS | 0.04 | -- | NS | 11.7 | 0.29 | 8.2 |

The repeated treatment every other day appeared to apply too much 2,4-D and caused a slight detrimental effect.

A pilot test was conducted in the field to evaluate the effect of repeated light treatments of 2,4-D in the field. The trial was planted July 7. Treatments began on August 1 and continued to September 13. The trial was harvested September 15. The heavy treatment (2/week) showed a slight visual effect of spreading the leaves in a more prostrate position. No visual effect was noted for the 1/week treatment. The harvest data (Table 11) indicate that one treatment per week had little effect on growth, but the two treatments per week had the same effect as on the seedlings in the greenhouse; i.e., a decrease in top growth and an increase in root growth. No attempt was made to measure cells in this test. The heavy treatment (2/week) interfered with the sugar reading, and we were unable to determine the sugar percentage.

Table 11. Top weight, root weight, and gross sugar for a control and two treatments of 2,4-D at 1/week and 2/week intervals. Each application was approximately 1/200 oz. 2,4-D per acre.

| Treatment | Intervals | Top Wt/plot g | Root Wt/plot g | % Sugar |
|------------|-----------|------------------|-------------------|------------|
| Control | -- | 9895 | 9517 | 12.0 |
| 2,4-D | 1/week | 9816 | 5700 | 11.7 |
| 2,4-D | 2/week | 9393 | 6968 | -- |
| LSD (0.05) | | 1336 | 1331 | 0.8 |

In summary the following conclusions were drawn:

- Very light doses of 2,4-D cause an increase in root yield.
- The point (concentration of 2,4-D) at which a positive effect is observed is very narrow. A slightly higher dosage causes harmful effects.
- This increase in root yield was largely due to increases in cell division rate and not due to increase in cell size.
- The photosynthate partitioning (root/shoot ratio) was altered by the 2,4-D treatments.
- Positive effects of 2,4-D are short-lived.

2. IAA - In this test, plants were sprayed with concentrations of IAA, ranging from 10 ppm to 1000 ppm, two weeks after planting and at weekly intervals for 3 weeks. Plants were harvested, weighed, and sectioned for cell size measurements one week after the last application of IAA. IAA appeared to have a similar effect of 2,4-D in that it caused a decrease in leaf weight, an increase in root weight, and this increase was due to an increase in cell division rate (Table 12). Effects were small, however, and didn't reach significance.

Table 12. Hypocotyl diameter, leaf and root weight, cell size and cell number for plants treated with different concentrations of IAA.

| Treatment | HD | Leaf Wt. g | Root Wt. g | Cell Size $\times 10^{-9}$ | Cells/ Radius |
|------------|-------|---------------|---------------|-------------------------------|------------------|
| 0 ppm | 202.1 | 5.36 | 0.86 | 2.03 | 123.4 |
| 10 ppm | 204.4 | 5.33 | 0.89 | 1.78 | 118.4 |
| 100 ppm | 207.5 | 5.20 | 0.92 | 1.72 | 131.7 |
| 1000 ppm | 201.2 | 5.12 | 0.93 | 1.96 | 123.6 |
| LSD (0.05) | 9.9 | 0.63 | 0.10 | 0.30 | 12.7 |

3. Dow 290 and Kinetin - Tests of these two hormones were conducted separately but are presented here together. These two tests were conducted in a similar manner as reported for 2,4-D and IAA, except cell size and cell number measurements were not made. Dow 290 is a herbicide similar to 2,4-D and had a similar effect; i.e., it increased root yield (Table 13). It didn't seem to have an effect on top yield except at high concentrations. This hormone is not as toxic as 2,4-D. Kinetin didn't give a consistent effect (Table 13); i.e., the data varied and showed no consistent trend.

Table 13. Hypocotyl diameter, top weight, and root weight of plants treated with different concentrations of Dow 290 and Kinetin.

| Treatment | HD | Top Weight | Root Weight |
|----------------|-------|---------------|----------------|
| <u>Dow 290</u> | | | |
| 0 ppm | 148.8 | 4.85 | 0.400 |
| 1 ppm | 148.3 | 4.61 | 0.391 |
| 10 ppm | 161.2 | 4.97 | 0.444 |
| 100 ppm | 146.2 | 3.49 | 0.392 |
| LSD (0.05) | 8.3 | 0.43 | 0.039 |
| <u>Kinetin</u> | | | |
| 0 ppm | 177.3 | 4.31 | 0.541 |
| 1 ppm | 173.9 | 3.99 | 0.503 |
| 50 ppm | 164.9 | 4.11 | 0.474 |
| 100 ppm | 175.5 | 3.37 | 0.530 |
| LSD (0.05) | 11.0 | 0.39 | 0.057 |

The hormones tested thus far had an effect of altering the photosynthate partitioning by decreasing the amount going to the leaves and increasing that going to the root. The increased photosynthates translocated to the root were used for increasing the number of cells. While these trends were consistent, they were very small and slight increases in the hormone caused an adverse effect on the plant.

IV. GROWTH ANALYSIS

PARTITIONING PHOTOSYNTHATE FOR GROWTH AND SUGAR ACCUMULATION IN SUGARBEET

J. C. Theurer

The yield of sugar from a crop of sugarbeets is determined by both the size of the roots and the percentage of sucrose in these roots. Unfortunately, an inverse relationship is apparent between sugar content and root yield. Selection for high yield usually decreases sucrose and selection for high sucrose decreases root yield. Since this is a barrier to improvement of sugar production, it points out that we need more basic knowledge concerning the mechanisms and the controlling sites of photosynthate partitioning in order to make effective progress in the development of superior varieties.

Leaf initiation and top growth, root expansion and enlargement, and sucrose storage all compete for the same photosynthate supply. Partitioning to top growth, to root growth, and to sucrose accumulation varies continuously throughout the growing season and is dependent upon the relative sink strength of the plant parts. It is evident that the top receives the major part of the total available photosynthate early in the growth season, and the root receives most of the photosynthate during the latter part of the growth period. However, the influence of the sink strength of the root and that of the top for sucrose production is not readily apparent.

In 1977, we conducted a grafting experiment to determine the site of photosynthate partitioning and to compare the effect of the top versus the root on growth and sugar accumulation. Reciprocal grafts were made between L19, high-sugar inbred, C17, high-yield inbred, and a fodder beet Blanca which was obtained from Kleinwanzleben Sugar Company, Einbeck, West Germany. Data gave evidence that both the top and the root influence sucrose accumulation, but that the root had the greatest influence. (See 1977 Research Report, page B33). In this experiment, the plants were grown in 6-gallon buckets inserted into the soil in the field. This may have restricted root growth. In addition, a severe curly-top infection became evident in the field in August, and by harvest the top growth of all plants showed evidence of poor growth except those where C17 (moderate curly-top resistance) was used as the scion. Roots of severe curly-top infected plants were smaller than anticipated, and we felt the data concerning partitioning to top and root growth was not a valid comparison.

In 1978 we again made reciprocal grafts to study photosynthate partitioning. One experiment was conducted in the field and another in the greenhouse. The four genotypes listed in Table 1 were used for the field experiment.

Table 1. Characteristics of Genotypes used in Grafts -
1978 Field Experiment

| Genotype | % Sugar | Root Size | Top Size |
|----------|---------|------------|----------|
| L19 | High | Small | Small |
| C17 | Medium | Large | Medium |
| Mangel | Low | Large | Medium |
| Chard | Medium | Very Small | Large |

In the greenhouse experiment, a high-sugar hybrid (HS) 28F1, and a high-yield hybrid (HY) 28D52 were used in place of L19 and C17 inbreds, respectively.

Seed of each genotype was planted in 3 x 3 x 13 cm Japanese paper pots in greenhouse beds. Seedlings to be used as stocks in grafts were thinned to a single plant per paper pot. Ten-day-old seedlings were used as stocks and seedlings in the cotyledon stage of development were used as scions. Each graft was made by making a vertical cut through the hypocotyl of the stock seedling, inserting a wedge-shaped scion, then attaching a woman's hair clip to hold the scion firmly in place. The grafted beets were transplanted into soil in a 6-inch pot and a plastic bag was placed over the top of the pot to maintain a humid atmosphere until union of the graft occurred. Plants were kept under a constant grow-lux light for the first week following grafting. Approximately 10 days after the graft was made, when union had occurred, the leaves were completely trimmed from the stock, plants were grouped into replications and were watered with an equal volume of a complete nutrient solution.

Plants for the greenhouse experiment were transplanted June 9 into 6-gallon buckets and randomized in eight replications on ground beds in a single bay of the greenhouse. The temperature was maintained at 75-85 F. Plants were harvested August 2, 1978.

In the field test the grafted beets were removed from 6-inch pots June 2 and planted directly into the soil in the field on 30-inch centers. There were 28 replications in the experiment. This test was irrigated at weekly intervals and managed similar to other field trials. Harvest was made September 6-7, 1978.

Immediately after beets were dug, the tops were separated from the roots and weighed. Tops were then dried in a forced-air dryer for 96 hours and reweighed to obtain the weight of the dry matter in the tops. Roots were washed by hand, air dried to remove surface water, then weighed. Sucrose content of the roots was determined from a shredded sample of the root portion of each grafted beet. The standard cold-digestion polarization method was used for determination of sucrose percentage. A sample of shredded root tissue was dried to a constant weight in an oven maintained at 100 C and used to determine total root dry matter and the sucrose percentage in the dry matter of the root.

Results

In all cases the chard scions produced a small, knob-like crown on the root of all other genotypes. By contrast, the crowns of all genotypes tended to engulf the chard root, giving a shape similar to a large table beet. It was also visibly obvious that the mangel contributed to increased root size with all other genotypes.

Greenhouse Experiment.

The leaf number, leaf area, fresh and dry weight of leaves and roots, and the sucrose percentage for the crown and root portions are given in Table 2.

Table 2. Leaf area, top and root weight, and sucrose % for grafted beets -
1978 Greenhouse Experiment

| CV | 28.8 | 19.9 | 26.7 | 16.1 | 27.2 | 24.2 | 9.6 | 12.5 |

Grafts with the sugarbeet genotypes as scions produced a significantly greater number of leaves than grafts with chard or mangel scions, regardless of the root stock. The chard stock caused an increase in leaf number, leaf area, and top weight with scions from all other genotypes. Conversely, the stocks of all other genotypes reduced the size of chard tops compared to the homogeneous chard/chard grafts (compare 385, 583, 708, versus 800 grams top weight).

The scions of sugarbeet hybrids and the mangel had a greater effect on top growth than their stocks. Chard showed the opposite effect as the stock exerted the greatest change in the amount of assimilate that was proportioned to top growth. As expected, chard had significantly the largest top and the smallest root development of the four lines used in the experiment.

The HY homogeneous graft had the largest root weight. Scions of all other genotypes tended to reduce the root weight of HY. The HY hybrid scion increased the root size of HS (81 vs. 94 grams). The root size of chard was increased by scions of all other genotypes.

Both scions and stocks of the HS hybrid increased the sucrose percentage of the other genotypes. The HY hybrid decreased the sucrose percentage of HS, but increased sucrose percentage of mangel and chard grafts. The mangel significantly decreased sucrose percentages of the sugarbeet hybrids. Table 3 shows the relative effects of root and shoot on sucrose percentage. It is apparent that the roots were primarily responsible for determining the proportion of photosynthate that was partitioned to sucrose storage.

Table 3. Effect of root and shoot on sucrose percentage -
1978 Greenhouse Experiment

| Genotype | | Percent Change | | | |
|----------|-------|----------------|-----|--------|-------|
| | | HS | HY | Mangel | Chard |
| HS | Scion | -- | +9 | 0 | +5 |

| | Stock | -43 | -22 | -19 | -- |

Field Experiment

The fresh weight and the total dry matter of the tops for all graft combinations are given in Tables 4 and 5, respectively. Correlation between fresh weight and dry weight was 0.87. The top weights for homogeneous grafts are listed and underlined on the diagonal of each table. The columns of the table show the growth effects of the scion of a given genotype on the root stock of all other genotypes in the study. The rows in each table show the effects of top growth as influenced by a common stock genotype.

Table 4. Fresh weight (kg) of tops of grafted beets

| Stock | Scion | | | |
|---------------------|-------------|-------------|-------------|-------------|
| | Chard | Mangel | C17 | L19 |

| L19 | 258 | 203 | 149 | <u>180</u> |
| Overall mean = 255.8 | | LSD = 69 | | |

As expected, the homogeneous chard graft had significantly the largest top at harvest. L19 high-sugar inbred developed the smallest top of

homogeneous grafts. The chard scion grew significantly slower on rootstocks of L19, C17, and mangel (3.49, 3.49, 2.35 versus 6.28), indicating that more photosynthate was being utilized for root growth than when the chard top was developed on its own rootstock. The chard stock caused an increase in top growth with scions of the other genotypes (e.g. 2.27 versus 1.18 for L19, Table 4). This demonstrates an internal mechanism in chard for partitioning more photosynthate for growth of the shoot, and also competition between plant parts of different genotypes for the available photosynthate. There was little effect on top growth when tops of the sugarbeet genotypes L19 and C17, or the mangel, were interchanged.

The effects that the root and shoot exert on partitioning of photosynthate to dry matter production in the top can be estimated from a comparison of the influence of the scions and stocks in reciprocal grafts. These effects are shown in Table 6. Values listed are the percent change in top growth due to different scions or stocks, compared to the growth of homogeneous grafts. In most instances, the scions or stocks influenced photosynthate partitioning; however, neither the root nor the shoot consistently exerted the greater influence on partitioning. In general, scions of chard and mangel had a greater influence than their stocks. L19 tended to show greatest influence due to stocks.

Table 6. Effects of root and shoot on top weight (dry matter basis).

| | | Chard | C17 | Mangel | L19 |
|--------|-------|-------|-----|--------|-----|
| Chard | Scion | -- | +80 | +63 | +43 |
| | Stock | -- | +45 | 0 | +63 |
| C17 | Scion | -47 | -- | +18 | +13 |
| | Stock | -35 | -- | -24 | -15 |
| Mangel | Scion | -67 | -31 | -- | -17 |
| | Stock | -46 | + 7 | -- | +23 |
| L19 | Scion | -51 | -30 | -12 | -- |
| | Stock | -57 | - 7 | -25 | -- |

The root portion fresh weight and dry weights are shown in Tables 7 and 8. Correlation between these weights was .98. The mangel homogeneous graft had the largest root weight and chard homogeneous graft had the smallest root weight. All four genotypes were significantly different in their root weight on both a fresh weight and a dry weight basis. Almost all of the reciprocal grafts were significantly different. Both the scions and the stocks had some influence on root weight. The mangel stocks greatly increased the root weight of a plant regardless of the scion top (Compare the first-row weights in Tables 7 and 8 with weights of homogeneous grafts down the diagonal of the respective table.) From the standpoint of the effect of the scions, C17 scion increased, L19 decreased, and chard had little effect on the root weight of the mangel. Neither mangel, C17 or L19 scions increased the root weight when they were grafted to chard stocks (Compare weights on last row of each table).

Table 7. Fresh weight (g) of roots of grafted beets

| Stock | Scion | | | |
|----------------------|-------------|------------|------------|------------|
| | Mangel | C17 | L19 | Chard |
| Mangel | <u>1160</u> | 1746 | 872 | 1165 |
| C17 | 408 | <u>639</u> | 470 | 391 |
| L19 | 333 | <u>480</u> | <u>317</u> | 476 |
| Chard | 115 | 149 | <u>122</u> | <u>178</u> |
| Overall mean = 563.8 | | | LSD = 149 | |

Table 8. Total dry matter (g) of roots of grafted beets

| Stock | Scion | | | |
|---------------------|------------|------------|-----------|-----------|
| | Mangel | C17 | L19 | Chard |
| Mangel | <u>138</u> | 216 | 123 | 174 |
| C17 | 65 | <u>110</u> | 90 | 68 |
| L19 | 59 | <u>85</u> | <u>66</u> | 91 |
| Chard | 20 | 27 | <u>36</u> | <u>33</u> |
| Overall mean = 87.5 | | | LSD = 29 | |

The comparative effects that the root and shoot exert on partitioning photosynthate for root growth were estimated by noting differences caused by scions or stocks, compared to the homogeneous grafts (Table 9). With the exception of C17 and mangel reciprocal grafts, the stocks had a significantly greater effect than scions in changing root weight. We can conclude from these results that the root sink strength is primarily responsible for determining the amount of total photosynthate that is partitioned to the roots.

Table 9. Effects of root and shoot on root weight (dry matter basis)

| | | % Change | | | |
|--------|-------|----------|-----|-----|-------|
| | | Mangel | C17 | L19 | Chard |
| Mangel | Scion | -- | -41 | -11 | 139 |
| | Stock | -- | +96 | +86 | +427 |
| C17 | Scion | +56 | -- | +29 | - 18 |

| L19 | Scion | -11 | -18 | -- | + 9 |
| | Stock | -57 | -23 | -- | +176 |
| Chard | Scion | +26 | -38 | +38 | -- |
| | Stock | -86 | -75 | -45 | -- |

Sucrose percentage in the fresh roots and sucrose percentage in the root dry matter for reciprocal grafts is given in Tables 10 and 11. Correlation between sucrose on a fresh and dry matter basis was 0.91. On a fresh weight basis all four homogeneous grafts were significantly different in their sucrose percentage. On a dry weight basis L19 and C17 were significantly higher in

sucrose content than chard or the mangel beets. L19 increased sucrose percent as both scion and stock for all other genotypes. C17 decreased sucrose content of L19, but increased the sucrose percentage of chard and mangel. The mangel root greatly reduced sucrose percentage regardless of the genotype used as scion.

Table 10. Sucrose percentage in roots of grafted beets

| Stock | Scion | | | |
|---------------------|-------------|-------------|------------|------------|
| | L19 | C17 | Chard | Mangel |
| L19 | <u>16.3</u> | 13.3 | 13.4 | 13.2 |
| C17 | 13.0 | <u>11.5</u> | 11.8 | 11.0 |
| Chard | 10.9 | <u>8.7</u> | <u>9.4</u> | 8.2 |
| Mangel | 8.4 | 6.9 | <u>6.8</u> | <u>5.9</u> |
| Overall mean = 10.5 | | | LSD = 1.1 | |

Table 11. Sucrose percentage of total dry matter in roots of grafted beets - 1978 field experiment

| Stock | Scion | | | |
|---------------------|-------------|-------------|-------------|-------------|
| | L19 | C17 | Mangel | Chard |
| L19 | <u>73.6</u> | 72.4 | 71.8 | 69.1 |
| C17 | 68.9 | <u>66.9</u> | 72.1 | 68.5 |
| Mangel | 59.0 | <u>56.3</u> | <u>52.3</u> | 46.7 |
| Chard | 52.6 | 49.3 | <u>49.1</u> | <u>52.1</u> |
| Overall mean = 61.3 | | | LSD = 7.5 | |

The effects of the root and shoot on partitioning photosynthate were estimated from the effects of scions and stocks in the reciprocal grafts (Table 12). With one exception (chard-mangel grafts) the stock was significantly most important in effecting change in sucrose content. We can conclude that the root is the site and has greater influence than that of the top in partitioning of photosynthate for sucrose storage.

Table 12. Effects of root and shoot on sucrose percentage in total dry matter

| | | % Change | | | |
|--------|-------|----------|-----|--------|-------|
| | | L19 | C17 | Blanca | Chard |
| L19 | Scion | -- | + 3 | +13 | + 1 |
| | Stock | -- | + 8 | +37 | +33 |
| C17 | Scion | - 2 | -- | + 8 | - 5 |
| | Stock | - 6 | -- | +38 | -41 |
| Blanca | Scion | - 2 | + 8 | -- | - 6 |
| | Stock | -20 | -16 | -- | -10 |
| Chard | Scion | - 6 | + 2 | -10 | -- |
| | Stock | -29 | -26 | - 6 | -- |

Discussion

Three reciprocal grafting experiments, made with diverse yield and sucrose genotypes, have demonstrated that partitioning of assimilate in the sugarbeet is determined by both internal controls and by competitive interaction of root and top sink strengths. Similar results were observed in sugarbeet-chard grafts by Thorne and Evans (1) and Rapaport and Loomis (2).

Both the root and the shoot have an influence on the photosynthate partitioning mechanism. However, our experiments showed that the root is primarily responsible and has the greatest influence on partitioning of photosynthate for root growth and for sucrose storage. Recent experiments by Wyse (unpublished data) support the conclusion that the major site for partitioning of photosynthate to root growth versus sucrose storage is within the root. He found that increasing photosynthate supply by CO₂ enrichment, increased total dry matter production, and decreasing photosynthate supply by shading decreased total dry matter production. Neither treatment, however, altered the partitioning between sucrose and non-sucrose dry matter in the root. These data suggest that maximum sucrose production will be achieved when we can alter the partitioning of photosynthate within the root so as to increase the ratio of sucrose to non-sucrose dry matter.

THE EFFECT OF PHOTOSYNTHATE SUPPLY ON PARTITIONING
WITHIN THE ROOT SINK OF SUGARBEET (Beta vulgaris)

Roger Wyse

Introduction

In recent years a major research effort has been directed toward improving photosynthetic efficiency in agronomic plants. As yet these studies have revealed little promise for improving plant productivity by increasing photosynthetic rates per se either through chemical or genetic manipulation. Receiving less research emphasis, but of major importance, is the allocation of photosynthate between sink regions within the plant. The ability of a plant to partition a high proportion of fixed carbon into the economically important sink is an important and genetically controllable factor (Synder et al. 1978). Although source-sink relationships are not well understood, there is considerable evidence that the ability of the sink to absorb photosynthate may play an important role in regulating rates of photosynthesis. For example, in grafting studies, when the high capacity root sink of sugarbeet was grafted to the spinach beet top, net assimilation rates were enhanced over that of spinach beet tops on spinach beet roots (Thorne and Evans, 1964). In short-term experiments, Swanson (1978 personal communication) has shown that the photosynthetic rate of source leaves increases as the size of the source is decreased. In short-term studies by Servaites and Geiger (1974), translocation rates increased in proportion to photosynthetic rates. Therefore, it would appear that the photosynthetic and translocation systems are not normally limiting productivity in sugarbeet.

In sugarbeet the economically important product is sucrose. Therefore, it is the objective of agronomists and genetists to maximize the sucrose content of the root. Based on growth chamber experiments, Ulrich (1954) proposed that only excess photosynthate above that required for structural growth of the root sink is stored as sucrose. However, modeling work by Fick et al. (1975) would indicate that the mechanisms controlling partitioning within the root sink for sucrose or non-sucrose structural carbohydrates is not well understood. Our objective was to determine the effect of photosynthate supply on the partitioning of sucrose within the sugarbeet plant.

Photosynthate supply can be regulated in field experiments by manipulating ambient CO₂ and light levels within the sugarbeet canopy. The CO₂ effects on plant productivity are well understood and are used on a commercial scale to increase greenhouse production (Wittwer, 1964). In growth chamber experiments with sugarbeet, Ford and Thorne (1967) found that increasing CO₂ levels to 1000 ppm increased photosynthetic rates in sugarbeet by 40%. This enhanced photosynthate supply increased root weight in preference to top weight. However, the differences were relatively small. Watson et al. (1972) showed that shading of sugarbeet plants throughout the growing season did not change the partitioning of sucrose in the root between sugar storage and structural dry matter. In studies reported here, CO₂ enrichment and shading in the field were used to manipulate photosynthate supply, and the effect on photosynthate partitioning within the root determined.

Materials and Methods

An adapted sugarbeet cultivar (AH-10, Amalgamated Sugar Company) was planted on May 12, 1978 with 55 cm rows. The plants were thinned on June 13 to a spacing of 10 cm within the row. All fertilizer was applied preplant as 1050 kg/ha of 16-20-0 (N-P-K). The plots were irrigated to field capacity at weekly intervals from emergence until approximately three weeks prior to harvest. On July 12 shading and CO₂ enrichment treatments were initiated.

Shading Experiment. Black nylon mesh having a 50% shading efficiency was suspended 75 cm above the soil surface with 1/8-inch steel cables on wooden posts. Treatments were arranged in a randomized block design with 8 replications. The plots consisted of three rows 5 m long running east and west. Only the north two rows were harvested. The percent shading was determined on a clear day, at approximately solar noon, using an Eppey Light Meter.

CO₂ Enrichment Experiment. Two-row plots 5 m long were surrounded (top open) by 1 m high, 0.1 mm thick natural polyethylene plastic on wooden frames. Cross baffles of polyethylene were installed at 1.5 m intervals within the chambers to retard mixing of the enriched atmosphere with outside air. CO₂ was generated in a chamber (2 m³) containing a propane fired CO₂ generator (Stuppy Greenhouse Supply) and a centrifugal fan with a delivery of 27 m³/min of air. The fan and generator were controlled by a time clock to operate between 800 and 1800 hours. The CO₂ enriched air was distributed to the individual chambers through a central wooden duct connected to 4-inch perforated plastic tubes (black plastic drainage "tile") down the center of each plot. To supplement the level of CO₂, fifty pounds of dry ice were added daily to the mixing chamber at 900 hours. The combination of the CO₂ generator and the dry ice maintained an atmosphere of 600 to 850 ppm within the plant canopy between 800 and 1800 hours. A complete air exchange within the plant canopy occurred approximately every two minutes. CO₂ levels both in the distribution system and in the plant canopy were measured by gas chromatography.

The plots were hand harvested on October 25. Measurements of root and top fresh weights were made in the field. Subsamples for determining the dry matter content of tops were obtained at that time. The roots were analyzed for sucrose content by polarimetry using the cold digestion technique used by the sugarbeet industry. Root dry matter was determined on a pulp sample obtained with a Spreckels Saw. All dry weights were determined after drying to constant weight at 100 C.

Data were analyzed using a randomized complete block design. Means followed by one asterisk were significant at the 5% level. Those followed by two asterisks were significant at the 1% level.

Results

Reducing incident radiation by 50% reduced total dry matter production by approximately 31% (Table 1). Root dry weight was reduced 38%, and as a result, the root-shoot ratio (R/S) was slightly lower in the control. Therefore, shading reduced the amount of photosynthate allocated to the root and also changed the partitioning ratio between root and shoot. The reduction in

R/S due to shading is a typical response to shading found in many plants. The apparent mass of the tops was visually greater in the shaded plants, leaves were larger and petioles were longer. However, the fresh weight differences were not nearly so apparent on a dry weight basis.

Table 1. Effect of (50%) shading on dry matter production of field grown sugarbeets.

| | Total | Root | R/S |
|---------|---------|------|------|
| | kg/plot | | |
| Control | 9.4 | 5.4 | 1.46 |
| Shaded | 7.2 | 3.9 | 1.23 |
| | ** | ** | ** |

The dry matter content of the shaded roots was slightly, although non-significantly lower than that of the control (Table 2). Sucrose contents on a fresh weight basis were not significantly different. Sucrose content on a dry weight basis is an index of partitioning between sucrose and non-sucrose dry matter within the root. The sucrose contents on a dry weight basis were not significantly different between the two treatments. Therefore, reducing the photosynthate supply by shading did not alter the partitioning of sucrose within the root.

Table 2. Effect of shading (50%) on photosynthate partitioning within the root of field grown sugarbeets.

| | Dry Matter | Sucrose Content | |
|---------|------------|-----------------|------------|
| | | Fresh Weight | Dry Weight |
| | | Percent | |
| Control | 22.0 | 15.8 | 72.1 |
| Shaded | 21.6 | 15.8 | 73.0 |
| | ns | ns | ns |

CO₂ Enrichment. Increasing the ambient levels of CO₂ within the canopy increased total dry matter production by 29% (Table 3). Root dry weight was increased 32% but there was no difference in the R/S ratio. Therefore, the increased photosynthate supply enhanced dry matter production but did not alter partitioning between root and shoot.

Table 3. Effect of CO₂ enrichment on dry matter production of field grown sugarbeets.

| | Total | Root | R/S |
|--------------------------|---------|------|-----|
| | kg/plot | | |
| Control | 10.2 | 5.9 | .98 |
| CO ₂ Enriched | 13.2 | 7.8 | .93 |
| | ** | ** | ns |

Percent dry matter was not significantly different between the control and the CO₂ enriched treatment (Table 4). Sucrose content on a fresh weight basis was slightly higher in the CO₂ enriched treatment. However, on a dry weight basis, the sucrose contents were not significantly different. Therefore, enhancing the photosynthate supply to the root by CO₂ enrichment did not alter the partitioning of the photosynthate between sucrose and non-sucrose dry matter.

Table 4. Effect of CO₂ enrichment on photosynthate partitioning within the root sink of field grown sugarbeets.

| | Dry Matter | Sucrose Content | |
|--------------------------|------------|-----------------|------------|
| | | Fresh Weight | Dry Weight |
| | | percent | |
| Control | 21.9 | 16.2 | 73.9 |
| CO ₂ Enriched | 22.4 | 16.7 | 74.5 |
| | ns | * | ns |

Discussion

These data suggest that although root growth is directly related to photosynthate supply, the partitioning within the root is independent of this photosynthate supply. These results confirm those of Watson et al. (1972) which showed that reducing photosynthate supply by shading did not alter sucrose content of sugarbeet roots on a dry weight basis. Previous work by Wyse (unpublished results) showed an increase in sucrose content on a dry weight basis from May through August. However, after September 1, no additional increase occurred. His data indicate that the sucrose to non-sucrose dry matter ratio may be genetically controlled. Although sucrose content on a fresh weight basis continues to increase, photosynthate partitioning reaches a constant level. Enhancing photosynthetic rates of sugarbeet plants would be a technique to increase total root yield but would not enhance sucrose content. Since it is the desire of the sugarbeet processor to process a minimal tonnage of roots in order to recover a maximum amount of sucrose, it would seem logical that the plant breeder should attempt to manipulate photosynthate partitioning, and in particular, photosynthate partitioning within the root sink itself. The goal of such an approach would be to maximize the allocation of the translocated photosynthate for sucrose storage. It is clear that such attempts should concentrate on modifying the sucrose to non-sucrose ratio within the root.

IMPORTANCE OF CELL SIZE AND VASCULAR DENSITY ON ALLOCATION
OF CARBON IN SUGARBEET ROOTS

Roger Wyse

Introduction

The sugarbeet plant has a relatively simple vegetative source-sink system. The translocated photosynthate is stored without modification as opposed to more complex systems which produce starch or proteins in the sink region. Therefore, it is a good organism for studying source-sink relationships and photosynthate partitioning.

The objective of this research is to define the mechanism controlling photosynthate partitioning between sucrose and non-sucrose dry matter within the root sink of sugarbeet. Grafting studies between genotypes possessing varying potentials for sucrose storage indicate sucrose content, and the growth potential of the root sink is controlled in the root. Therefore, our studies have concentrated on sink metabolism.

Materials and Methods

Our approach is to use comparative morphological and biochemical studies of genotypes within Beta vulgaris. The genotypes used are as follows:

1. Experimental high sugar hybrid: High sucrose content but low root yield.
2. Commercial hybrid: Intermediate sucrose content and intermediate yield.
3. Fodder beet: Low sucrose content and high root yield.

Sucrose content on a dry weight basis is an index of photosynthate partitioning between sucrose and non-sucrose dry matter within the root sink. The genotypes selected for study demonstrated considerable differences in their ability to store a high percentage of the translocated photosynthate as sucrose (Table 1).

Table 1. Root sucrose contents of the
genotypes at maturity

| | Fresh Weight | Dry Weight |
|------------|--------------|------------|
| | percent | |
| High Sugar | 17.9 | 72.4 |
| Fodder | 8.9 | 63.5 |
| Commercial | 16.7 | 70.2 |

All plants utilized in these studies were field grown. Specific methods are listed with the appropriate table or figures.

Results

Comparative Morphology. The genotypes capable of storing high levels of sucrose have more vascular rings and relatively narrow bands of interzone parenchyma tissue between rings. In contrast, the high yield genotypes have fewer vascular rings and wide bands of interzone parenchyma tissue (Figure 1). These differences exist throughout the growing season (Figure 2). The wider rings of the fodder beet root are a result of both an increase in the number and size of cells (Figure 3).

Figure 1. Cross-sections of sugarbeet (high sucrose) and fodder beet (low sucrose) roots. Note greater number of rings and narrower bands of interzone parenchyma in the sugar types.

Therefore, genotypes capable of partitioning a high portion of the translocated photosynthate for sucrose storage have small cells, more vascular rings and narrow bands of parenchyma cells between vascular rings.

Localization of Sucrose. Most of the sucrose stored in the root sink is localized in the parenchyma cells near the vascular bundles (Figure 4). The interzone parenchyma cells are lower in sucrose than parenchyma cells near the vascular bundles. The sucrose content of the interzone cell is inversely related to its distance from the vascular bundle. Interzone parenchyma cells contain higher levels of potassium, amino acids and reducing sugars than cells near the vascular bundle. This difference in cellular composition is particularly apparent in the fodder beet.

The differential composition between vascular and parenchyma tissue is apparently the result of an osmotic adjustment. The soluble solids content of the interzone cells is lower than that of cells near the vascular bundle (Table 2); however, osmotic concentrations in the two areas were not significantly different. Therefore, the depressed sucrose content in the interzone cells

is replaced by potassium, amino acids and reducing sugars. The osmotic concentration of root cells is not fixed but increases throughout the growing season as sucrose content increases. The osmotic concentration also varies between genotypes in direct relation to their sucrose content (Figure 5). The root water potential decreases with increased sucrose content primarily as a result of a greater osmotic potential. Turgor remains essentially constant. Therefore, osmotic concentration does not limit the amount of sucrose that can be stored.

Table 2. Evidence for osmoregulation between vascular and parenchyma tissue

| | Vascular | Interzone Parenchyma | |
|------------------------------|----------|-------------------------|----|
| <u>Osmolality, mmols/ml</u> | | | |
| High Sugar | .658 | .676 | ns |
| Fodder | .389 | .352 | ns |
| Commercial | .622 | .593 | ns |
| <u>Soluble Solids, mg/ml</u> | | | |
| High Sugar | 204 | 190 | * |
| Fodder | 107 | 75 | * |
| Commercial | 210 | 210 | ns |

The distribution of sucrose between the free space, cytoplasm and vacuole was determined using compartmental flux analysis (Table 3). The fodder beet maintained a slightly greater proportion of sucrose in the free space (FS) and less in the vacuole than did the other genotypes. However, it is clear that the majority of sucrose is stored in the osmotic compartment (cytoplasm and vacuole).

Table 3. Compartmentation of sucrose in root cells of three Beta vulgaris genotypes

| | Total mg/gm | FS | Cyto percent | Vacuole |
|------------|----------------|----|-----------------|---------|
| High Sugar | 142 | 14 | 12 | 74 |
| Fodder | 53 | 20 | 12 | 68 |
| Commercial | 127 | 15 | 12 | 72 |

Sucrose Uptake from the Apoplast. No differences were observed between genotypes in their ability to accumulate sucrose from a 5 mM solution (Table 4). In fact, on a cell surface area or a per cell basis, fodder beet was capable of absorbing sucrose at a faster rate than were the sugar types. Sucrose uptake from the apoplast into the vacuole of storage parenchyma cells is directly proportional to the concentration of sucrose in the free space between 5 and 500 mM concentration (Figure 6).

Figure 2. Mean width between vascular rings of three *Beta vulgaris* genotypes during a 22-week growing season.

Figure 3. Mean cell diameter and number of cells between vascular rings 2 and 3 of the tap root of three genotypes of *Beta vulgaris* during a 22-week growing season. Cell size was determined by direct measurement in prepared tissue sections by light microscopy.

Figure 4. Differences in chemical composition between vascular and parenchyma tissue in three Beta vulgaris genotypes.

Figure 5. Total, osmotic, and turgor potentials in roots of four Beta vulgaris genotypes. Potential measurements were made using psychrometric techniques on tissue cores (4 mm x 5 mm). Tissue was a mixture of vascular and interzone parenchyma cells.

Table 4. Combined sucrose uptake into cytoplasm and vacuole by root disks from a 5 mM sucrose solution

| | Uptake* |
|------------|---------|
| High Sugar | 317 |
| Fodder | 325 |
| Commercial | 317 |

Temp. 25 C, .005 m sucrose

*nmols/2 hr/20 disks

Figure 6. Relationship between concentration and rate of sucrose uptake by disks of sugarbeet root tissue. Disks (1 x 4 mm) were incubated for 3 hours in aerated media, washed to remove free space sucrose and the total counts remaining in the tissue determined.

Conclusions

Cell size and distance between vascular rings play a key rôle in determining the partitioning of photosynthate between sucrose and non-sucrose dry matter in the roots of Beta vulgaris. Small cells and narrow rings would have the folowing effects:

1. Increase the amount of cell wall per unit volume of tissue thus reducing the diffusive resistance within the apoplast. This lower

resistance coupled with a shorter diffusive path would expose a greater proportion of the cells within the sink region to high concentrations of sucrose in the free space.

2. Osmotic volumes are decreased and, therefore, osmotic concentrations are more easily adjusted. A lower osmotic volume would limit "storage space" if the osmotic potential were limited to a fixed value. However, as the data indicate, there is an osmotic adjustment within the tissue throughout the growing season. Therefore, sucrose storage is not limited by osmotic concentration.
3. A disadvantage of small cells may be an increased maintenance respiration resulting from higher osmotic gradients and greater volume of cytoplasm. A second disadvantage is the greater amount of dry matter allocated to cell wall.

Since uptake of sucrose is proportional to the external sucrose concentration, photosynthate partitioning between sucrose and non-sucrose dry matter in the root sink can be explained in large part by cell size and diffusive resistance (Figure 7). Those genotypes having small cells and narrow rings have a high proportion of cells in areas near the vascular bundles where free space sucrose concentrations are highest. The additional sucrose absorbed as a result of these higher external sucrose concentrations is stored in the vacuole.

Figure 7. Illustration of cell size-ring width effects on sucrose partitioning within the root sink of Beta vulgaris.

SEASONAL ACCUMULATION RATE FOR
HIGH SUCROSE GENOTYPES

J. C. Theurer and D. L. Doney

There is a marked difference in genotypes for sucrose percentage on a fresh weight basis. Lines that have high sucrose content early in the growing season generally are the ones that exhibit high sucrose at harvest in October (see 1976 Research Report, p. B43-B50). L19 inbred, a high sugar genotype, has shown a greater rate of sugar accumulation during the growing season than any other line we have tested. This line also contributes to increased sucrose in all hybrids where it has been used as a parent. In 1975 and 1976 June harvests, L19 had a lower sucrose percentage than several other lines. However, by September 1, the L19 inbred and L19 hybrids have shown significantly higher sucrose than any of the other lines being tested. The question is raised as to whether this behavior of the rate of sucrose accumulation is peculiar to the L19 genotype, or do other genotypes show similar behavior for sucrose accumulation.

High sucrose lines were obtained from USDA and sugar company sources and were compared at Logan in 1978. Ten hybrids and four inbreds were included in the field test in a split-block experiment with inbreds in one group and hybrids in another within each replicate. Two rows, (1 inbred and 1 hybrid), were seeded for a buffer between the inbred and hybrid units of each replicate. Individual plots consisted of two 22-inch rows 20 feet long with beets approximately 12 inches apart in the row. GWD2 and L20xL33 are high yield varieties that were included in the test as checks.

Twenty-four replicates were planted for each entry, and four harvests were made of six replicates per entry at each harvest. The dates of harvest were July 13, August 10, September 13, and October 12. Twenty competitive beets were taken from each plot at the first harvest for sucrose analysis, using the standard cold digestion pol method. Ten competitive beets were taken from each plot for each of the three subsequent harvests. Root weight sucrose percent and dry matter were also determined.

RESULTS

The root yield for the inbreds and hybrids is given in Table 1. There was a significant mean increase from 1.5 tons per acre at H1 to 15.5 tons per acre at H4. Significant differences in root yield were also noted between entries for each harvest. GWD2, L20xL33, and C17 had the highest root yield, as expected. Beta varieties also had relatively high yields. Root yield for H4 was affected by the degree of curly top disease of the respective entries.

Sucrose percent on a fresh weight basis is given in Table 2. Sucrose content increased in a somewhat linear manner. The rate of accumulation was greater the latter part of July and first part of August than it was during August and September. The four inbreds in the experiment showed similar patterns of sugar accumulation as was previously observed in 1975 and 1976 (Figure 1). L19 again showed lower sucrose percentage on the first harvest but had a far more rapid accumulation rate for the balance of the season than did L53 or F6. L53xL19 and 638R were the only hybrids that were consistently higher in sucrose percent than the two high yield checks, GWD2 and L20xL33. L53xL19 and ACH14 showed similar accumulation patterns with the greatest increase in percent sucrose from H1 to H2. L53xL19, Beta 1345, and 638R had the greatest increase

| C.V. | 9.2 | 5.8 | 5.3 | 4.8 |

in sucrose during the growing season (H1 to H4), being respectively 9.2, 8.2, and 8.5 percent. Beta 1237 and AH12 had the slowest rates of sugar accumulation of the hybrids, increasing respectively 2.7 and 2.9 percent between H1 and H2 and 7.0 and 7.4 percent between H1 and H4. The pattern of sucrose accumulation was generally similar for all hybrids. Figure 2 shows the accumulation pattern for high sucrose lines, 638R and L53xL19, for the high yield check, GWD2, and for the mean of all hybrids. The sugar accumulation patterns for all other hybrids, not plotted, would be between 638R and GWD2.

The sucrose percent of the dry matter increased on the average from 55% for H1 to 74% for H4 (Table 3). On the average, there was a 23% increase in D.M. sucrose percentage from H1 to H2, a 5% increase from H2 to H3, and a 6% increase from H3 to H4. Thus, the sucrose percentage in the total dry matter showed the greatest rate of increase between H1 and H2, as was observed for sucrose on a fresh weight basis. L19 had the lowest D.M. sucrose percentage at H1 and one of the highest percentages at H4. This inbred also showed the greatest rate of increase (30%) from H1 to H2 and, for the season, H1 to H4, (45%). Very few D.M. sucrose percentages were significantly greater, or less, than the overall mean at each harvest, and no entry consistently showed the highest, or the lowest, D.M. sucrose for the four harvests. Of note, was the observation that the high yield lines, GWD2 and L20xL33, had as high a D.M. sucrose percentage as L53xL19, or 638R; the hybrids having the greatest sucrose percentage on a fresh weight basis. Likewise, C17 (high yield) and L19 (high sucrose) inbreds showed no difference in sucrose on a dry weight matter basis.

Figure 1. Seasonal accumulation of sucrose in inbred lines (fresh weight basis).

Figure 2. Seasonal accumulation of sucrose for two high-sugar hybrids, one high-yield hybrid, and the mean for 10 hybrids.

DISCUSSION

Results of this experiment confirm those of previous years. On a fresh weight basis, sucrose accumulation shows a linear pattern during the growing season, with the greatest rate of sugar storage occurring the latter part of July and the first part of August. On a dry weight basis, sugar accumulation is rapid during the above cited period and levels off for the balance of the season. Differences between sucrose and yield types are primarily due to the water content of the cells, since the D.M. sucrose percentage for the two types is very similar. High yield types have larger cells and more water in the tissues than sucrose types. The non-significance of D.M. sucrose percentage suggests that it would be difficult to select for high sucrose content on a dry matter basis. These data support other studies at the Logan Station which show that photosynthate is partitioned in the root to sucrose storage and root growth at approximately the same percentage, regardless of whether the genotype is a sucrose or yield type.

The sucrose accumulation pattern of L19 would indicate that it is probably genetically different than other sucrose lines. This was also inferred by previous studies wherein L19 was the only genotype that consistently showed high osmotic potential regardless of the stage of plant growth. Other genotypes only showed high-osmotic potential when beets were mature. The sugar accumulation pattern of L19 was not very evident in the L53xL19 hybrid in 1978. However, in 1976 tests, L53xL19 hybrid did show the typical extremely high rate of sugar accumulation at H2 versus H1, as consistently observed with L19 inbred.

V. INSECT RESISTANT STUDIES

SELECTION FOR SUGARBEET ROOT MAGGOT RESISTANCE

J. C. Theurer, C. C. Blickenstaff, and D. L. Doney

Selection for resistance to damage by the sugarbeet root maggot, Tetanaps myopaeformis was initiated in 1975 as a cooperative project of USDA-AR scientists at Logan, Utah, and Kimberly, Idaho. The third cycle of selection for high and low damage was made this year for two populations, 25A1 and 25D47.48.

High-damage and low-damage roots were selected from open-pollinated and selfed progenies in July 1977 in the root maggot nursery at Kimberly. Selfed and open-pollinated seed increases were made of the selected roots in the greenhouse and in isolation chambers at Logan during the winter of 1977-78.

Open-pollinated seed of 25D47.48 low damage, 25A1 low damage, 25A1 high damage, and the parent population were planted in the spring of 1978 at Kimberly in 3-row plots of 10-hill rows with hills 1 foot apart in the row. Entries were randomized in 20 replications. Five selfed progenies from plants showing low damage to the root maggot, and three selfed progenies from high damaged plants were compared in a second experiment. Entries were planted in a single 10-hill row with plants 1 foot apart in the row and replicated 20 times.

Maggot damage and vigor readings were made on all entries during the third week of July. Damage was visually rated by scoring roots on a scale of 1 (low) to 5 (high). Vigor was rated on a scale of 1 (poor) to 5 (good).

RESULTS

Damage and vigor ratings for the open-pollinated, selected population (3rd cycle), and the parent are given in Table 1. Selection was effective since both the low- and the high-damage selections were significantly different from the rating of the parent population. Selection for low damage in the third

Table 1. Root maggot damage and vigor ratings for open-pollinated populations. 1978.

| Entry | Maggot Damage Rating | Vigor Rating |
|---------------------|-------------------------|-----------------|
| 25D47-48 Low Damage | 1.83 | 3.8 |
| 25A " " | 1.79 | 3.6 |
| 25A1 High " | 2.45 | 3.4 |
| 25A1 Parent | 2.04 | 3.4 |
| Mean | 2.03 | 3.6 |
| LSD | 0.17 | 0.28 |
| C.V. | 13.3 | 12.4 |

cycle did not show additional improvement over that of the second cycle in relation to improvement in percent of the parent (Figure 1). This suggests that we may have reached a plateau using mass selection, and that other breeding methods that capitalize on non-additive genetic variation will be required for further

improvement in maggot resistance. The infestation in 1978 may have been less than that of previous years. The parent ratings in 1976, 1977, and 1978 were, respectively, 2.80, 3.08, and 2.02.

Figure 1. High and low selection for maggot damage in relation to original parent population.

Populations selected for low damage also exhibited better vigor than the parent population, or the high damage selection (Table 1). The correlation was -0.73 for vigor vs damage rating.

Maggot damage and vigor ratings for selfed lines are given in Table 2. The low-damage selections from the previous year had lower maggot ratings than the high-damage selections; however, only one selection, 40F9, was significantly different than the high-damage maggot lines. With one exception, 40G8, the low-damage selections, had significantly better vigor than high-damage selections. Correlation between these variables was -0.67 . Stand was not good in these plots and, no doubt, had an influence on the amount of root maggot damage. There was an average of 6 plants per line in each replicate; however, plots ranged from 3 to 10 plants each.

Selection was also initiated this year in another heterogeneous population. Recurrent selection and inheritance studies on maggot resistance are planned for the next few years.

Table 2. Maggot damage and vigor ratings for selfed progenies selected for high and low damage - 1978.

VI. SUGARBEET DISEASES

SYSTEMIC INSECTICIDE TREATMENT OF RESISTANT AND SUSCEPTIBLE SUGARBEETS TO REDUCE CURLY TOP

D. L. Mumford

During the past three years, there has been a rapid increase in the amount of acreage in the Intermountain Area planted with sugarbeet cultivars that are quite susceptible to beet curly top virus (BCTV). This has occurred because some susceptible cultivars have yielded higher than resistant cultivars in the absence of curly top. In 1977, sugarbeet growers were reminded of the severe losses BCTV can cause when a localized epidemic occurred in southern Idaho.

Systemic insecticides have been shown to be effective in controlling the sugarbeet leafhopper and reducing losses due to BCTV (1) (4). There is a need for information on whether systemic insecticide treatment would prevent disease loss in susceptible sugarbeets as effectively as host resistance does in resistant sugarbeets under severe curly top conditions. This study was undertaken to determine the comparative effectiveness of systemic insecticide treatment in reducing losses due to BCTV in a susceptible, a moderately susceptible, and a resistant sugarbeet.

MATERIALS AND METHODS

A susceptible cultivar (Beta 1345), a moderately susceptible cultivar (Great Western D-2), and a resistant cultivar (Amalgamated AH-12) were tested in a split-plot design. Main plots consisted of phorate (Thimet) at 1.3 lbs. active ingredient per acre applied 4" below the seed, aldicarb (Temik) at 2 lbs. active ingredient per acre applied as a 2-to-3-inch band at the seed level (Ruskin method), and an untreated check. Subplots consisted of four 25-foot rows of the three cultivars listed above. Main plots were replicated six times. The test was planted late (May 23, 1978) to favor the development of severe curly top symptoms. A severe curly top level was induced in the plots by methods previously described (3). Approximately 12,000 viruliferous leafhoppers were distributed throughout the plots on June 27, two weeks after thinning plants to one plant per foot of row.

On July 14 and on August 2, the percentage of infected plants in the center two rows of each subplot was determined. Thirty competitive roots (those having an adjacent root on either side) were hand-harvested from the center two rows of each plot on September 28. The roots were hand-topped, washed, weighed, and the sucrose percent was determined.

RESULTS

By August 2, maximum infection (99%) had been reached in the susceptible cultivar (Table 1). At this time, the reduction in infection in Thimet-treated plants over untreated checks of AH12, D2, and 1345 was 110, 64, and 71, respectively. Temik treatment did not consistently reduce infection. This was, undoubtedly, due to the ineffectiveness of the method of insecticide application used in this study.

Table 1. Effect of systemic insecticide treatment on curly top infection, root yield, and sucrose content of resistant and susceptible sugarbeets.

| Variety | Treatment | Infection | | Root Yield T/A | Sucrose % |
|-----------------------------------|-----------|-----------|----------|----------------------|--------------|
| | | 7/14 % | 8/2 % | | |
| AH12 (Resistant) | Thimet | 17 | 30 | 11.8 | 16.77 |
| | Temik | 33 | 56 | 9.4 | 16.22 |
| | Untreated | 28 | 63 | 8.6 | 15.98 |
| D2 (Moderately Susceptible) | Thimet | 28 | 56 | 11.7 | 15.90 |
| | Temik | 56 | 93 | 6.1 | 15.58 |
| | Untreated | 65 | 92 | 6.7 | 15.83 |
| 1345 (Susceptible) | Thimet | 42 | 63 | 10.6 | 15.42 |
| | Temik | 60 | 95 | 3.7 | 15.23 |
| | Untreated | 72 | 99 | 2.3 | 14.70 |
| LSD (P = 0.05) | | | | 1.9 | 1.04 |

Thimet treatment below the seed resulted in significant increases in root yield over no treatment for all three cultivars (Table 1). As expected, root yield increase was greatest in the susceptible cultivar. The results show that, under conditions present during this study, below the seed application of Thimet increased root yield 32%, 75%, and 361% in AH12, D2, and 1345, respectively. Differences in root yield between the three cultivars treated with Thimet were not significant.

There were no significant differences in sucrose percent between insecticide treated and untreated plants of any of the three cultivars. However, AH12 had significantly higher sucrose than 1345; probably due to differences in curly top severity.

DISCUSSION

No attempt was made in this study to make direct comparisons, either between Thimet and Temik insecticides or between different methods of application with the same insecticide. Other studies (1) (2) have shown that Thimet, Temik and other insecticides are effective in reducing curly top losses. Each insecticide has advantages and disadvantages such as phytotoxicity, longevity of effectiveness, nematocidal properties, and cost. The application of Temik with the seed was included in this study to test an alternative to below the seed applications which some consider detrimental to good germination in the Intermountain Area.

Although this study shows that insecticide treatment offers considerable protection from curly top to both resistant and susceptible sugarbeets, some cautionary considerations should be kept in mind. The widespread planting of curly top susceptible sugarbeets will probably increase the threat of severe curly top disease years due to the increased presence of hosts that are excellent reservoirs for the virus. Environmental factors, such as temperature and moisture, influence the effectiveness of insecticides resulting in severe loss potential with a combination of susceptible host and failure of insecticide treatment.

ABSTRACTS OF PAPERS PUBLISHED OR APPROVED FOR PUBLICATION AND
GERMPLASM RELEASES AND REGISTRATIONS, 1978

HECKER, R. J. and E. G. RUPPEL. Release of sugarbeet germplasm resistant to Rhizoctonia root rot. Official joint release of the USDA-SEA, Beet Sugar Development Foundation, and Colorado State University Experiment Station, February 28, 1978.

Five multigerm, rhizoctonia root rot resistant sugarbeet germplasms were released for use in breeding and variety development programs. All the germplasms are moderately resistant to cercospora leaf spot, they flower after a short induction (easy bolting), and they are largely self sterile.

FC 702/4 is a product of two cycles of recurrent selection for resistance to rhizoctonia root rot following four cycles of mass selection for resistance from a synthetic derived from an obsolete variety (GW 359).

FC 702/4 (4X) is the C₃ colchicine-induced tetraploid conversion of FC 702/4, without additional selection.

FC 705 is a rhizoctonia resistant synthetic developed by four cycles of recurrent selection for resistance from FC 701 (previous release) which had been developed by four cycles of mass selection from GW 674-56C (obsolete variety).

FC 706 is a heterogeneous strain, mass selected for resistance from the OP₂ generation of five diverse strains, all of which had been subjected to three to five cycles of selection for resistance. Characteristics among these five strains included black root, leaf spot, and botrytis resistance, monogerm, high root yield, high sucrose, and some genes from *Beta maritima*. The strain has potential for development of diverse rhizoctonia resistant strains.

FC 707 is a product of one cycle of selection for resistance from an inter-pollinated pool of superior progeny lines, each of which had been subjected to five cycles of selection. Their origins had been from high production experimental synthetics.

In inoculated field trials over 2 years, these five strains have exhibited good resistance to a highly virulent root-rotting strain of *Rhizoctonia solani*. FC 705 and FC 707 have resistance superior to the previously released strain FC 703. FC 702/4 and FC 706 have slightly less resistance than FC 703. These strains all have relatively good general combining ability as tested by a common set of male sterile testers. In the absence of rhizoctonia root rot, the sugar yield of these strains was below that of commercial varieties; hence, these strains are not released for grower use. These strains have potential as pollinators or sources of pollinators in hybrids, and as sources of genes for rhizoctonia resistance.

HECKER, R. J. and G. A. SMITH. Release of sugarbeet germplasm. Official joint release of the USDA-SEA, Beet Sugar Development Foundation, and Colorado State

University Experiment Station, February 28, 1978.

FC 704 is a diploid multigerm, red fleshed, rhizoctonia resistant sugarbeet. It is a product of three cycles of mass selection in both the vegetative and flowering stages for intensification of red color in roots and tops followed by two cycles of mass selection for resistance to root rot caused by *Rhizoctonia solani*. The roots, petioles, and leaves are deep red. The source of this line was a heterogeneous population known as the "German red beet," acquired about 1940 by the Great Western Sugar Company from the German firm Kleinwanzlebener Saatzucht AG. FC 704 has relatively high root yield, but has very low sucrose content and thin juice purity. The source population is the only *Beta vulgaris* germplasm found which has a significant amount of inherent resistance to rhizoctonia root rot. Other sugarbeet strains with similar levels of resistance have been derived only through intense breeding. This relatively high level of inherent resistance is the primary reason for release of this material. It is not known if the resistance in FC 704 is genetically the same as the resistance accumulated in previously released rhizoctonia resistant sugarbeet strains. In inoculated replicated tests, FC 704 had about 25% healthy roots compared with 0 to 3% in commercial hybrid varieties, and 50% in the most resistant developments from the Fort Collins breeding project. The source population of FC 704 has been used as a top cross general combining ability tester; FC 704 may be similarly useful. FC 704 is susceptible to cercospora leaf spot and curly top, and flowers after a relatively short induction.

SCHWEIZER, E. E. Control of broadleaf weeds in sugarbeets with glyphosate. Proc. Western Society of Weed Science 1978. 31:122.

Annual broadleaf weeds that escape cultivation and herbicidal treatments applied in sugarbeet compete with the crop. Since even low densities of weeds can reduce root and sucrose yields, we conducted field studies to determine the effectiveness of glyphosate [*N*-(phosphonomethyl) glycine] to control or minimize the competitiveness of low densities of common lambsquarters, kochia, and redroot pigweed. These weeds were spaced alternately within the row to achieve broadleaf densities of 0, 6, 12, 18, and 24 plants per 30.5 m of row. On June 23, glyphosate was sprayed 10 cm above the sugarbeet canopy with a recirculating sprayer at 1.7 kg/ha and at a volume of 187 L/ha. The average height of sugarbeets was 45 cm, common lambsquarters 85 cm, kochia 70 cm, and redroot pigweed 40 cm. Many redroot pigweed plants and a few other broadleaf plants, were not sprayed because they were not tall enough to intercept any spray. Of those that were sprayed, some died within 2 weeks and others continued to die slowly, until by late September, 58% of the common lambsquarters, 77% of the kochia, and 65% of the redroot pigweed had died. Less than 3.5% of the sugarbeet plants were injured by glyphosate and only 0.2% of those died. Weed competition was reduced significantly by glyphosate. Thus, root yields were reduced only 8, 10, 15, and 19% where the original densities were 6, 12, 18, and 24 plants per 30.5 m of row. In a comparable study in which these broadleaf weeds were not treated with glyphosate, root yields were reduced 20, 35, 43, and 54%, respectively.

STEINKAMP, M. P., S. S. MARTIN, L. L. HOEFERT, and E. G. RUPPEL. Ultra-structure of lesions produced by *Cercospora beticola* in leaves of *Beta vulgaris*. Accepted for publication in *Physiol. Plant Pathol.*

The fungus *Cercospora beticola* Sacc. incites a leaf spot disease of sugarbeet (*Beta vulgaris* L.). Lesion formation was studied by electron microscopy. One week after inoculation, the fungus was established in the intercellular spaces of the mesophyll and degenerative changes had occurred in cells near infection sites. Visible necrotic spots were produced as these lesions enlarged. During the degenerative sequence cell membrane systems and organelles were disrupted; affected cells quickly collapsed and became necrotic. After 3 weeks a boundary zone with two regions separated central necrotic tissue from apparently unaffected, healthy tissue outside the lesion. Two types of cell wall apposition occurred, one a localized callose-type in the lesion center, and the second a generalized wall thickening in the inner boundary zone. Electron-dense material occluded intercellular spaces in the outer boundary zone. During most phases of the disease, hyphae bridged intercellular spaces or were attached to and followed the contours of host cell walls. Only late in the disease, long after host cells were necrotic, were hyphae observed within largely disintegrated host cell walls.

SMITH, G. A., R. J. HECKER, and S. S. MARTIN. The effects of ploidy level on the components of sucrose yield and quality in sugarbeet. Approved by SEA for publication in *Crop Sci.*

Comparisons of 2X, 3X, and 4X sugarbeet (*Beta vulgaris* L.) lines and hybrids were made to determine the effects of ploidy level on sucrose yield and quality components in equivalent and non-equivalent hybrid populations.

The relative order of importance for the components of recoverable sucrose was generally the same for all three ploidy levels, with root weight having the greatest path coefficient direct effect and juice purity the least.

Purity percent generally decreased as ploidy level increased; this purity decrease was accompanied by increases in the quantity of nonsucrose chemical components in the extract.

Significant differences were found between reciprocal equivalent 3X hybrids for both yield and quality components. Recoverable sucrose yield of triploids produced from tetraploid female plants [3X(4X♀)] averaged 17% greater than that of the reciprocal 3X(4X♂) hybrids. The same 3X(4X♀) triploid hybrids also were lower than their reciprocal equivalents in extract concentrations of Na, K, and total N, with decreases of 9%, 17%, and 12%, respectively. When components are expressed in mg per 100 g sucrose, the corresponding decreases were 13%, 20%, and 16%, respectively.

SMITH, G. A. Sugarbeet. Ch. 45. In Hybridization of Crop Plants. Am. Soc. Agron. Press, Madison, WI. Probable date of publication, April 1979.

The chapter describes the hybridization techniques used in sugarbeet research programs and in commercial hybrid seed production. Techniques

described include, plant culture, plant preparation for hybridization, special environmental requirements for floral induction and use of male sterility. A description of all wild relative species and their hybridization potential, and a complete listing of all identified genes of sugarbeet are included.

SMITH, G. A., E. G. RUPPEL, and J. O. GASKILL. Registration of sugarbeet germplasm with resistance to Cercospora or Cercospora and curly top. Accepted for publication in Crop Sci.

The following lines which have been described in their respective release documents were developed by the USDA, SEA, in cooperation with the Beet Sugar Development Foundation and the Colorado State University Experiment Station. All of the lines except FC 902 are monogerm. FC 902 is a multigerm line developed for resistance to cercospora-curly top and intended for use as a pollinator.

All of the lines with a 500 designation, i.e. FC 504, were developed for resistance to cercospora leaf spot. Lines with 600 designation, i.e. FC 605, were developed for combined resistance to cercospora and curly top. Germplasm lines and their registration numbers are as follows:

| | |
|-------------------------------|-----------------------------|
| FC 902 (Reg. No. GP 41) | FC 506 (Reg. No. GP 46) |
| FC 504 (Reg. No. GP 42) | FC 506 CMS (Reg. No. GP 47) |
| FC 504 CMS (Reg. No. GP 43) | FC 604 (Reg. No. GP 48) |
| FC 502/2 (Reg. No. GP 44) | FC 604 CMS (Reg. No. GP 49) |
| FC 502/2 CMS (Reg. No. GP 45) | FC 605 (Reg. No. GP 50) |
| | FC 605 CMS (Reg. No. GP 51) |

RHIZOCTONIA ROOT ROT RESEARCH AND RESISTANCE BREEDING (BSDF Project 20)

Rhizoctonia Field Research, 1978.--R. J. Hecker and E. G. Ruppel.

Our 1978 field research on resistance to *Rhizoctonia* in sugarbeet was conducted on our BSDF-leased farm where we also conduct the cercospora leaf spot field research. This was the first crop year of the 3-year renewed lease on the farm.

The area of the farm devoted to rhizoctonia root rot research is on a 4-year rotation (beets, barley, barley, fallow). Our 1978 experimental area was the first time we have returned to an area previously used for rhizoctonia research, which was 1974. There was a noticeable, but not a practically significant amount of infection by *Rhizoctonia* prior to inoculation.

The experiments in the rhizoctonia root rot test area were inoculated July 24 with a tractor-mounted 4-row granule applicator. The dry, ground barley-grain inoculum of *Rhizoctonia solani* (R-9) was broadcast in a band over each row at the rate of 8 grams per 6.1 m of row in a split application (opposite directions of travel for each application). One-row plots 6.1 m long and 56 cm apart were planted May 21. Thinning was done between June 12 and 20. The roots were lifted and individually rated for severity of rot between September 11 and 15. The disease index (DI) ratings were based on a scale of 0 to 7 (0 = no evidence of infection, 7 = plant dead and extensively decomposed). The percentage of healthy roots were those with DI ratings of 0 and 1.

Our root rot epidemic in 1978 was relatively mild compared to other years. However, significant death loss did occur in susceptible populations by harvest time. We feel that the assessments for disease resistance were adequate and accurate.

Our rhizoctonia research can be classified into three general categories.

- 1) Breeding for improved resistance and developing genetic information about resistance, and information on the utilization and incorporation of resistance into commercial hybrid varieties.
- 2) Studying the effect of various cultural practices and environmental conditions on the severity of root rot, and making applied recommendations in these areas.
- 3) Basic research on the pathogen itself and on interactions of pathogen with genotype, cultural practice, environment, etc.

Succeeding sections of this report relate our 1978 accomplishments in these categories.

Evaluation of Contributed Lines.--E. G. Ruppel and R. J. Hecker.

Separate randomized complete block designs with five replications were used to evaluate a total of 57 contributed lines from American Crystal, Great Western, Holly, and Utah-Idaho Sugar companies for resistance to *Rhizoctonia solani*. In each test, cultivars FC 703 and GW 674-56C, resistant and susceptible to *R. solani*, respectively, were included as checks. Results of each company's test were statistically analyzed and sent to company breeders, thus, they will not be reproduced here. The mean disease index (DI) across tests for cv FC 703 on a scale of 0 to 7 was 2.0, whereas for the susceptible check the mean was 4.3. The range in DI means for all company lines was 2.1 to 6.6. Mean percentage healthy roots (0 + 1 DI's) was 53% for FC 703 and 12% for GW 674-56C. The range in percentage healthy means for company lines was 0 to 52%. Mean percentage harvestable roots (DI's 0, 1, 2, and 3)

was 87% for FC 703 and 44% for GW 674-56C. The range in percentage harvestable roots for company lines was 19 to 89% (mean = 56%).

Breeding for Increased Resistance to Rhizoctonia Root Rot.--R. J. Hecker and E. G. Ruppel.

Sugarbeet production losses from rhizoctonia root rot continue to occur in a variable pattern. In certain areas and in certain years infection and losses seem to be much greater than in others. Reports, as well as our own observations, would indicate that losses due to rhizoctonia root rot were relatively severe in 1978. In a few isolated cases, rhizoctonia root rot has been the major factor for growers going out of the beet-growing business. It appears likely that certain beet production areas, which tend to have a chronic rhizoctonia problem, will require the incorporation of rhizoctonia resistance into the hybrid varieties used in those areas. This means that we need to continue the rather intense effort to further increase the resistance of germplasm made available to industry breeders, and to help develop information to make the incorporation and use of this resistant germplasm more efficient. However, the rate of breeding progress and the current levels of resistance in the best germplasms in our program indicate that we should arrive, in the foreseeable future, at a high level of resistance and then be able to reduce the rhizoctonia resistance breeding effort.

We currently use three breeding methods for the improvement of resistance, namely, recurrent selection, mass selection, and pedigree breeding (including inbreeding). We sometimes overlap the methods, or may switch breeding lines from one method to another depending on potential, resources, etc. At the same time we are doing some backcross incorporation of resistance into monogerm, type 0, and cytoplasmic male sterile lines. Recurrent selection appears to have the greatest potential with respect to increasing resistance and maintaining desirable genetic characteristics including combining ability, which will make the resultant germplasm readily useful in commercial breeding programs. However, our resources are limited, hence, only a few of the most promising breeding lines can be included in the recurrent selection program. Less promising or newer breeding lines are carried in the mass selection program which requires considerably less resources.

Our most recent breeding developments, as well as various other materials of interest are evaluated each year in our inoculated rhizoctonia root rot nursery for the assessment of their resistance. Table 1 lists those multi-germ lines of greatest interest in the 1978 tests. The most resistant line in this group was FC 705, a new line having been released during 1978. It is a Syn 4 developed from 4 cycles of recurrent selection in FC 701. The next 4 lines with disease indices of 1.4, and entry 592 with a DI of 1.5, are all relatively vigorous and should have potential as pollinators of experimental hybrids. Entry 571, with a DI of 1.5 is from the Fargo rot resistant line F1002, which was developed by Dr. Bugbee from FC 701/4. Other lines of interest are entries 567, 570, and 589 with DI's of 1.7, 1.8, and 2.3, respectively. These entries all have some potential as useful pollinators.

The most resistant entry of all is among the monogerm group in Table 2. Entry 577 (DI = 1.1) has been our most resistant line for the last 2 years.

This line has resulted from selection in segregating generations of a cross between some of our rhizoctonia resistant multigerms and a pool of monogerm type O LSR-CTR lines. This population is segregating for monogerm; entry 573 (DI = 1.6) is a monogerm type O selection from this population, whereas entry 574 (DI = 1.6) is the first back-cross cytoplasmic male sterile (CMS) equivalent. In the process of selection and concentration of resistance in these materials, a significant amount of inbreeding has been done and these particular lines have reduced vigor and are agronomically unattractive due

to the long thin root shape and a tendency for the root to grow out of the ground. The release of some of these materials is anticipated in 1979. Even though they are not agronomically attractive, they are the most resistant germplasm in the world. Hence, they need to be made available to breeders as soon as possible.

Table 2. Rhizoctonia resistance of breeding lines which are monogerm or segregating for monogerm, and commercial type materials.

The commercial-type materials listed in Table 2 are included for relative assessments and comparisons. The most resistant line in this group, EL-42 (entry 589, DI = 2.3), resulted from a program of crossing and selection of Fort Collins rhizoctonia resistant material with East Lansing material by Dr. Hogaboam. The commercial varieties in this group can be classed as susceptible, although there are significant differences among those that are the least and the most susceptible. The pollinator C813 and C17 (entries 604 and 603) with DI's of 4.8 and 5.2, respectively, are among the most susceptible entries in the test which, undoubtedly, contributes to the high level of susceptibility of US H10B (entry 599, DI = 4.6), of which C17 is the multi-germ pollinator.

Those lines included in Tables 1 and 2 were those of greatest interest among the total of 95 entries in the experiment. A number of the lines are relatively diverse and represent some new sources of resistance. In general, the breeding lines that remain in the program are those few which show some degree of response to selection pressure. Included in the program over the years were many lines which failed to respond and were dropped. From the number of lines that have been dropped, and especially from the hundreds of sources evaluated for resistance, it appears that most sugarbeet lines have essentially no genes for resistance to *Rhizoctonia*.

Observations and results from our selection and breeding program continue to re-enforce our hypothesis that resistance is multigenic. Also the resistance that we have developed would appear to be horizontal resistance, in that we know of no *Rhizoctonia* strain to which germplasm from the Fort Collins resistance breeding program has been found to be susceptible. The hypothesis of horizontal resistance in these materials gains credence as more people test our germplasms against their indigenous strains of *R. solani*.

Each year, we test some of our more promising multigermlines as pollinators of experimental hybrids. The production of a number of these experimental hybrids is reported in another section of this report.

Performance of Rhizoctonia Resistant Experimental Hybrids and Pollinators.--
R. J. Hecker and G. A. Smith.

The rhizoctonia resistant multigermlines coming out of our breeding program have several potential destinies; 1) direct use as a pollinator parent of a hybrid variety, 2) for crossing with other breeding lines and selection of high combining rhizoctonia resistant segregants, and 3) as a source of resistance for a backcrossing program. In order that our breeding developments have some potential for uses 1 and 2 we like to assess, preliminarily, their combining ability. Hence, we use a diverse group of CMS lines and pollinate them with different rhizoctonia resistant multigermlines. The performance of the best individual hybrids in our 1978 disease-free test is shown in Table 1. None of these experimental hybrids were significantly better than the check. Three were not significantly different than the check for recoverable sucrose per acre, while all the others in Table 1 produced significantly less sucrose per acre. Some of these experimental hybrids could be of value in a growing area with a serious rhizoctonia root rot problem, even though they may be inferior to the check used in this disease-free experiment. Further description of these hybrids and even limited quantities of seed might be available for those who may be interested in testing them further.

Table 1. The best experimental hybrids in the 1978 test of hybrids involving rhizoctonia resistant pollinators.

An assessment of the general combining ability of the rhizoctonia resistant pollinators is made in Table 2. These are adjusted means from a partial diallel experiment conducted in a 10 X 10 triple lattice with 6 replications. Those pollinators that appear in Table 2 were those which were involved in three or more of the experimental hybrids in the test. Among this group of rhizoctonia resistant lines used as pollinators, FC 703 would appear to have the best general combining ability for recoverable sucrose and root yield. FC 703 has been released. It is relatively heterogeneous and has potential for further improvement of its combining ability. Also included in Table 2 is the disease index of these pollinators from a separate inoculated test in the rhizoctonia root rot nursery. All of the pollinators were relatively good for rhizoctonia resistance except the synthetic derived from Afanasiev resistant selections. The most rhizoctonia resistant pollinators may impart adequate resistance when hybridized with susceptible females so that the resulting hybrids could be used advantageously in rhizoctonia root rot problem areas.

Table 2. Adjusted means of all experimental hybrids of the respective rhizoctonia resistant pollinators (disease free), and disease indices in a separate inoculated test (0 = no rot; 7 = plants dead).

Rhizoctonia Inoculation and Resistance Selection in the Seed Production Phase.--R. J. Hecker and E. G. Ruppel.

A new method of additional exposure of sugarbeets to a root-rotting strain of *Rhizoctonia solani* was tested in 1977 and 1978. The method consisted of the placement of ground barley-grain inoculum around the mother roots when they were transplanted to the field for seed production. Hence, this method allows a second exposure to *Rhizoctonia* within a single generation.

Roots used in 1977 and 1978 had been grown the previous year, harvested about October 1, trimmed as mother roots, and stored over winter in our refrigerated root storage building at about 4-5 C and 100% relative humidity. The roots came through the winter storage periods virtually free of storage rot and deterioration.

As shown in Table 1, on April 27, 1977, we planted a line with intermediate resistance to *Rhizoctonia*, and a mix of rhizoctonia susceptible lines into a specially isolated plot. For those plants that were inoculated, 0.4 or 0.8 g of inoculum was mixed into the top 5 cm of soil immediately around the root. The plants were watered immediately after planting. In 1978, two space isolations were used with 597 roots planted at one location, and 338 at the other. *Rhizoctonia* resistant breeding lines were used at these locations in an attempt to see if additional genetic progress could be made in lines that already were relatively resistant. Again, 0.4 g of inoculum was mixed into the top 5 cm of soil around each beet at planting time, and then the plants were thoroughly watered. The planting time was April 28 for the large isolation, and May 11 for the isolation with 338 roots.

The 1977 plot was considerably drier than that in 1978 because little, if any, precipitation was received in 1977.

In 1977, the plants in both the intermediately resistant line, and the susceptible lines succumbed very early to root rot and died; Table 1 shows the number of survivors on July 1. Since we had no interest in seed from the control plants, the plot was abandoned. In 1978 we decided to use the technique for selection in the two lines shown in Table 1. Since in 1977 there was no difference between 0.4 and 0.8 g of inoculum per plant, we used 0.4 g per plant in the 1978 isolations. By June 15, very little indication of infection was apparent, so a side dress of 0.4 g of inoculum per plant was applied by pulling the soil away from one side of the root to a depth of 5 cm, sprinkling the inoculum against the root, then replacing the soil and watering. However, one row in each isolation was left without this additional inoculation. In late June and early July, infection became abundant; however, some of the plants were flowering before infection became apparent. These plants were removed to eliminate their contribution to the pollen cloud. By harvest time (August 11), only those plants noted in Table 1 had survived, and essentially half of the survivors showed some sign of active rot in the roots. Seed was harvested in two groups, that from the rot-free roots, and that from those roots which showed some rot. The seed will be tested for resistance in the inoculated rhizoctonia nursery in 1979. At the time of seed harvest, there was no difference in survival between those rows that had been left without the additional side-dress inoculum and those that were reinoculated. Hence,

the initial inoculum at planting time was, undoubtedly, adequate. The 1978 plants became infected and succumbed to the infection much later than those in 1977. This may have been due to two reasons. The 1978 populations were considerably resistant, and moisture was much more abundant in 1978, due to over 15 cm of precipitation in May. Due to the rather late infection, the surviving plants, undoubtedly, received some pollination from plants that shed some pollen before they showed signs of infection.

Table 1. Surviving plants following *Rhizoctonia* inoculation of mother roots.

| Population and year and treatment | Roots planted | Surviving plants | | |
|---|------------------|------------------|-------------|-------|
| | | Some rot | Rot free | Total |
| <u>1977</u> | | | | |
| Intermediate Rhizoctonia Resistant Line | | | | |
| Control (no inoculum) | 50 | | | 40 |
| .8 g inoculum/plant | 25 | | | 2 |
| .4 g inoculum/plant | 25 | | | 0 |
| Mix of Rhizoctonia Susceptible Lines | | | | |
| Control (no inoculum) | 50 | | | 42 |
| .8 g inoculum/plant | 82 | | | 0 |
| .4 g inoculum/plant | 80 | | | 2 |
| <u>1978 (.4 g inoculum/plant)</u> | | | | |
| Rhizoctonia Resistant FC 703 | 597 | 11 | 16 | 27 |
| Mix of Rhizoctonia Resistant Lines | 338 | 8 | 6 | 14 |

Thus, the method did not result in a total elimination of genetic contribution by all infected plants; however, we believe the method provides significantly more selection pressure for resistance than a single exposure during vegetative growth. We believe the method might be used successfully with or without the roots having been inoculated in the vegetative stage. The two populations resulting from these intense selections will be tested and the results reported in 1979.

Effect of Cultivation Practice and Postemergence Herbicide on Intensity of *Rhizoctonia* Root Rot.--E. G. Ruppel and R. J. Hecker.

Observations have been made that forcing soil around and into sugarbeet crowns during cultivation and ditching operations may enhance *rhizoctonia* root rot infection. The objective of this study was to determine the real effect of this practice, and to determine how the cultural practices might be modified to reduce infection by *Rhizoctonia* without reducing the beneficial effects of the practice. In addition, the effect of a postemergence application of phenmedipham ('Betanal') and desmedipham ('Betanex') on root rot severity was investigated.

An area of our field nursery known to be heavily infested with *Rhizoctonia solani* in 1977 was selected for this study in 1978. Standard seedbed preparations were carried out, and cycloate ('Ro-Neet') at 3 lb active ingredient

(a.i.)/acre was broadcast and incorporated as a preplant herbicide 3 days before planting. Additionally, dry, ground, barley-grain inoculum of *R. solani* at 50 lb/acre was broadcast and incorporated to assure uniform dispersion of the pathogen across the experimental area. Manzate-treated sugarbeet seed of *Rhizoctonia*-resistant cultivar FC 703 and susceptible commercial cultivar Mono Hy A1 were planted on April 7 in a 2 X 2 X 2 factorial design with four replications of each treatment-cultivar-herbicide combination. Four-row plots were 20 ft long with 22 inches between rows. On June 12, a 1:1 mixture of 'Betanal'-'Betanex' (B & B) at 0.5 lb a.i./acre was applied on a 7-inch band as a postemergence herbicide. Plots were thinned to 25 plants/row on June 14. Just before layby, a final cultivation and ditching operation was performed which deposited soil into and around the crowns of the beets in half the plots. Beets in the remaining plots were cultivated similarly except that the beets were shielded from soil.

Roots from all plots were harvested on September 11 and rated for amount of rot on a scale of 0 to 7, with 0 = no rot and 7 = plants dead. A disease index (DI), a weighted average based on the number of plants in each class, was calculated for each plot. Sugarbeets in classes 0, 1, 2, and 3 were considered to be "harvestable," because such roots ultimately would be processed in the sugar factory.

B & B had no significant effect on the incidence or severity of rhizoctonia root rot. Mean DI's were 4.3 with, and 4.2 without B & B across cultivars and cultivation (ditching) methods. Root rot was approximately twice as severe in the susceptible as compared with the resistant cultivar regardless of treatment.

A significant increase in root rot severity occurred in plots in which the cultivation practice deposited soil into and around beet crowns regardless of sugarbeet cultivar (Table 1). The increased rot led to a 6% reduction in harvestable roots of the resistant cultivar and a 20% reduction in the susceptible cultivar. Obviously, cultivation and ditching operations should be performed to minimize the deposition of soil into sugarbeet crowns. Slower tractor speeds, or planting on preshaped beds might serve this purpose.

Table 1. Effect of soil deposition in crowns of resistant and susceptible sugarbeet on severity of rhizoctonia root rot.

| Cultivar | Hilling ¹ | DI ² | Harvestable ³ |
|---------------|----------------------|-----------------|--------------------------|
| | | | % |
| FC 703 | + | 2.9 a | 72 |
| (resistant) | - | 2.3 b | 78 |
| Mono Hy A1 | + | 6.5 d | 7 |
| (susceptible) | - | 5.2 c | 27 |
| ----- | | | |
| C.V. | | 8.5% | |

¹Hilling = deposition of soil into crowns via cultivation practices.

²Disease index (DI) on a scale of 0 to 7, with 0 = no rot and 7 = plants dead. Means of eight replications; all significantly different at *P* = 0.05 according to Duncan's multiple range test.

³DI classes 0, 1, 2, and 3 combined.

Longevity of Rhizoctonia in Debris of Infected Rotation Crops.--E. G. Ruppel.

Plants of barley, bean, corn, and sorghum growing in pasteurized soil were inoculated with a root-rotting isolate of *Rhizoctonia solani* (R-9) from sugarbeet by replacing the top 2 cm of soil in each pot with soil mixed with dry, ground, barley-grain inoculum. After 30 days, plants were harvested and stem portions bearing typical *Rhizoctonia* lesions were excised, washed, and bulked from like species. The excised tissue was air dried, ground in a mill, and stored in a refrigerator at 3-4 C. At 1, 2, 4, and 8 months of storage, samples of "debris" from each crop were used to inoculate 2-month-old sugarbeets. Sugarbeet roots were harvested after 30 days and scored + or - for root rot. Isolations from rotted roots were made to identify *R. solani* as the causal agent.

No rot occurred in sugarbeet inoculated with any infested debris stored for 1 or 2 months (Table 1). Debris from sorghum only induced rot after 8-months storage, whereas infested debris from the other crops was infectious after 4 months. Thus, *R. solani* remained viable for 4 to 6 or 8 months in debris from infected rotation crops. Additional studies will be made to determine the effect of different storage conditions on the longevity of the pathogen within crop debris.

Table 1. Ability of stored *Rhizoctonia*-infected debris of rotation crops to induce root rot in sugarbeet.

| Crop debris | Storage (months) | | | | |
|-------------|------------------|---|---|---|---|
| | 1 | 2 | 4 | 6 | 8 |
| Barley | - | - | + | + | + |
| Bean | - | - | + | - | + |
| Corn | - | - | + | + | - |
| Sorghum | - | - | - | - | + |

EPIDEMIOLOGICAL AND BIOLOGICAL INVESTIGATIONS
ON FUSARIUM YELLOWS OF SUGARBEET (BSDF Project 54)

Cultural Comparisons of Fusarium Isolates.--E. G. Ruppel.

Isolates of *Fusarium oxysporum* f. sp. *betae* from Oregon, Wyoming, and Colorado significantly differ in cultural pigmentation, growth rate, and spore production; however, all isolates were morphologically similar.

Maintenance of Fusarium Stock Cultures.--E. G. Ruppel.

Fusarium species often lose pathogenicity when subjected to repeated subculturing on nutrient media. The pathogenicity of *Fusarium* from sugarbeet was maintained for at least 1 year in soil cultures. Approximately 3 g of a sandy loam soil was mixed with 0.1 g dry, ground barley grain and placed in a screw-cap vial. Enough water was added to just moisten the soil, and then

the vials were capped and autoclaved. When the vials were cool, a recent single-spore culture of *Fusarium* was used to infest the soil. The vials were loosely capped and incubated at room temperature. In 2-3 weeks, fungal growth was abundant and the soil had dried to the point of separation from the wall of the vials. At this time, the caps were tightened and the vials were placed in the refrigerator for storage.

REPORT ON POWDERY MILDEW
(Former BSDF Project 50)

Occurrence of Sexual Stage of Powdery Mildew in the U.S. is Confirmed.--
E. G. Ruppel.

D. L. Coyier, O. C. Maloy, and J. C. Zalewski reported finding the ascigerous (sexual) stage of the sugarbeet powdery mildew in 1974. Their paper, presented at the Pacific Division Meeting of the American Phytopathological Society in 1975, has been received with some skepticism since the ascigerous stage was not subsequently seen again for 2 years. More recently, R. L. Forster of the University of Idaho related (*personal communication*) that he also had found the ascigerous stage in April 1977 on buried sugarbeet debris of the 1976 crop.

Neither Coyier et al. nor Forster tested ascospores for their pathogenicity to sugarbeet. However, I have examined a powdery mildew-infected leaf provided by Coyier from Malloy's original collection and, indeed, did find typical *Erysiphe* cleistothecia of varied ages imbedded and attached to the surface mycelium. I have no doubt that these were structures of the sugarbeet powdery mildew and not chance contaminants from other plants.

The correct name of the *Erysiphe* from sugarbeet is still in question. Weltzien (Phytopathol. Z. 47:123-128, 1963) in Germany gave the fungus the species name *betae*. But Coyier et al. concluded that morphological differences between the sugarbeet mildew and *E. polygoni* were not sufficient to warrant a new species. They point out that there are many cases in the Erysiphaceae where similar or even greater differences exist without assignment of specific rank. Table 1 shows the morphological variability encountered among various investigators in studies of the beet mildew. According to Blumer (Blumer, S. 1933. Die Erysiphaceen Mitteleuropas mit besonderer Berücksichtigung der Schweiz. Zurich.), *E. polygoni* cleistothecia have a mean diameter of 112 μ m, with 3 spores/ascus. Weltzien found equal numbers of 2- and 3-spored asci in the beet fungus, whereas I found 2-5, mostly 4, spores/ascus in the samples from England and France. Unfortunately, the cleistothecia found on the leaf provided by Coyier were not mature and did not contain asci with ascospores; however, a photograph of a cleistothecium made by Coyier showed at least 6 asci, each with 5-6 ascospores. Undoubtedly, more information is needed on the ascigerous stage of the U.S. isolates of *Erysiphe* from sugarbeet before species classification can be made.

Most powdery mildews are heterothallic and require two compatible mating types for the completion of the ascigerous stage. The paucity of cleistothecia on

²Means.

infected sugarbeet leaves from Washington (Coyier, Forster, *personal communication*; *personal observation*) is somewhat puzzling. Infected plants in Spain and England, and samples from England and France showed abundant and easily visible fruiting bodies over entire leaves. Conceivably, one of the necessary mating types of the sugarbeet *Erysiphe* occurs in extremely low frequency in the U.S., or it is less fit to compete in nature.

The occurrence of the ascigerous stage possibly can create a problem for breeders working toward resistance to the pathogen. The overwintering potential of ascospores is questionable, but the sexual stage would allow the formation of new fungal strains via genetic recombination.

CERCOSPORA/CURLY TOP RESISTANCE BREEDING RESEARCH AND LEAF SPOT EVALUATION (BSDF Project 25)

Leaf Spot Evaluations of Sugarbeet Lines Submitted by BSDF-Member Companies.--
E. G. Ruppel and G. A. Smith.

Separate randomized complete block designs with two replications were used to evaluate a total of 157 breeding lines submitted by American Crystal, Great Western, Holly, and Spreckels Sugar companies. Internal checks included *Cercospora*-resistant cultivar FC (504 X 502/2) X SP 6322-0, a susceptible synthetic, and cultivar SP 5822-0 having intermediate resistance to *Cercospora*. The nursery was planted April 14 and inoculated July 10. The epidemic developed uniformly and reached maximum severity on or about August 29 when leaf spot evaluations were made on our usual 0-10 scale. Mean ratings for the resistant check ranged from 1.5-3.3 across all tests (overall mean = 2.5), whereas the susceptible check ranged from 6.5-7.3 (overall mean = 7.0). The intermediate check ranged from 3.0-3.5 (overall mean = 3.3). Company lines ranged from 3.3-7.0. Results of the individual tests were tabulated and sent to each respective contributor.

Breeding for Resistance to *Cercospora* and Curly Top Virus, 1978.--G. A. Smith and E. G. Ruppel.

The leaf spot epidemic in our 1978 nursery was uniform and moderately severe. The leaf spot and/or curly top ratings for some of our breeding lines and experimental hybrids are presented in Table 1. Curly top ratings were taken in the 1978 curly top nursery at Logan, Utah under a moderate epidemic. As a result of our efforts to breed for combined resistance to both *Cercospora* and curly top virus, FC 606 (entry 1539) and FC 606 CMS (entry 1521) were officially released. These two lines were equal to or better than the resistant checks for both diseases in tests spanning 4 years. FC 606 CMS has demonstrated greater resistance to *Cercospora* than FC 606 T.O. Both lines are vigorous, and were excellent seed producers in Oregon. Another promising monogerm line (entry 1523) has shown very high resistance to *Cercospora* (equal or better than US 201). We synthesized the type 0 of this line, and both the CMS and type 0 lines were sent to Oregon for seed increase. These lines may be released in 1979 if seed production is adequate. The vigor and good seed producing attributes of lines such as FC 606 and FC 607 provides the breeder with the option of using these lines in the production of single-cross commercial hybrids. It is particularly noteworthy that, if these lines are used in single-cross hybrids, the number of genes controlling resistance that are transferred from the original parental line to the hybrid theoretically will be double that transferred in a 3-way top-cross hybrid.

SUGARBEET QUALITY IMPROVEMENT RESEARCH (BSDF Project 53)

Evaluation of Reciprocal Triploid Commercial European Varieties.--G. A. Smith.

Several recent reports have indicated that triploids synthesized using tetraploid monogerm male steriles are more productive than triploids synthesized using diploid male steriles. Most of these reports have compared non-commercial experimental lines. In 1978 we tested two commercial European triploids (French origin) against 3 adapted U.S. varieties. It is not known whether the two triploids were reciprocal equivalents or unrelated reciprocal triploids. The test was conducted with 5 replications at the Colorado State University Agronomy Farm. Results of the test are presented in Table 1. No significant differences between the reciprocal triploids were found. However, both triploids out-yielded the diploids for root weight. Although sucrose was generally low in the test (likely due to excess nitrogen fertilizer), all three diploids showed significantly higher sucrose % than the triploids.

Table 1. Performance of two reciprocal triploids and 3 commercial diploids. The average performance of 5 replications.¹

Predicting Thin Juice Purity.--S. S. Martin, R. J. Hecker, and G. A. Smith.

There have been numerous attempts to assess sugarbeet "quality," defined in various ways by various authors. Burba (1975; ref. 5 in Table 1) has summarized many of these approaches. Ideally, quality embodies both chemical and physical properties of the sugarbeet, and often it is judged in relation to recoverable sucrose at a particular factory. Because not only the beets' characteristics but also the design and operating characteristics of the factory enter into consideration, a quality measure of this type must be individually developed for each situation. However, it often has been accepted that measurement of synthetic thin juice purity (TJPUR) by methods similar to those developed by Carruthers and Oldfield is an adequate (though imperfect) measure of sugarbeet "quality" at harvest. Prediction of TJPUR by means of chemical analyses of other components of various extracts also has been attempted by several authors. We have begun an investigation of TJPUR prediction, in which we plan to compare several published

Table 1. Comparison of purity prediction equations vs. measured laboratory thin juice purity in one experiment (n=80).

(All other equations are calculated with lead-clarified filtrate data.)

prediction methods (models) with measured TJPUR data from experiments including different genotypes, years, nitrogen levels, population densities, and extracts. We also will derive for each experiment the best multiple regression prediction equation, and compare to this the performance of published models and of models derived by us for other experiments. An example of the approach will be illustrated here with data from a single experiment.

Summarized in the upper portion of Table 1 are five published TJPUR predictive equations and two unpublished equations derived from other Fort Collins experiments. Each of these is based on sodium (NA), potassium (K), and amino nitrogen (AMN) measurements in lead-clarified filtrate. Sodium and potassium were determined by flame photometry with a lithium internal standard, and amino N was analyzed spectrophotometrically using ninhydrin. Equations 8 and 9 of Table 1 are the standards for comparison, derived by multiple regression from data of the same experiment, the first in lead-clarified filtrate (the data used in all the predictors above) and the second in aluminum-clarified filtrate. Actual laboratory thin juice purity was determined on the 80 samples of this experiment, and each predictive equation or purity model was compared for its ability to predict the measured purity of each sample.

Thin juice purities predicted by equation 8 were highly correlated with corresponding measured thin juice purities ($r = 0.86$). About 74% of the variability in measured thin juice purity can be accounted for by the relationship given; the inclusion of betaine in the equation increased R^2 by only 0.5. A more complex multiple regression equation derived from the same experiment but including eight variables (Na, K, amino N, total N, nitrate, chloride, betaine, and sucrose) increased R^2 to only 76.

Other subsets of chemical components may predict purity nearly as well as sodium, potassium, and amino N. For example, in this experiment nitrate was the variable accounting individually for the greatest proportion of variation in measured purity ($R^2 = 56$). A predictive model based on nitrate, amino N, and sodium gave $R^2 = 72$, almost as high as that of equation 8, and amino N and sodium together (excluding potassium) also showed $R^2 = 72$.

Although the coefficients differed, a purity model based on Na, K, and amino N in aluminum-clarified filtrates was as satisfactory as the equivalent model for lead-clarified filtrates (equations 9 and 8, respectively, in Table 1).

Although all of the seven thin juice purity models derived from data of other experiments predicted purities that were well correlated with measured purities in this experiment, most consistently either over- or under-predicted the actual values. Only equation 5 accurately predicted the actual thin juice purity mean, and predicted purity values that did not differ significantly by paired-sample t-test from measured purities. However, it is probable that yet another set of data will be best fit by a different one of the seven models. In further work we will explore the effect of several agronomic variables on these purity models, and the potential for a broadly applicable purity model.

Comparison of Aluminum Chloride and Lead Subacetate Clarification of Sugarbeet Brei Extracts. III. Analysis of Diverse Experimental Material.--
S. S. Martin and R. J. Hecker.

Lead-clarified and aluminum-clarified filtrates were compared in an experiment that included four sugarbeet cultivars (from a low-sucrose, low-purity type to a high-sucrose type) and two levels of nitrogen fertility. Analytical methods were described in Sugarbeet Research, 1977 Report. Although data analysis is not yet completed, preliminary comparisons of means and correlations coefficients between the two extract types are summarized in Table 1.

Table 1. Comparison of chemical constituents in aluminum- vs. lead-clarified sugarbeet extracts. [n-288]

| Extract component | Correl. coeff. r | -----Component concentration ¹ ----- | | | |
|-------------------|------------------------|---|------|--------------------|------|
| | | Lead-clarified | | Aluminum-clarified | |
| | | Mean | s.e. | Mean | s.e. |
| Sucrose | 0.99 | 14.73 | 0.12 | 14.70 | 0.13 |
| Sodium | 0.97 | 10.1 | 0.24 | 10.0 | 0.24 |
| Potassium | 0.95 | 21.2 | 0.32 | 20.5 | 0.32 |
| Amino nitrogen | 0.88 | 5.8 | 0.09 | 6.4 | 0.09 |
| Total nitrogen | 0.67 | 23. | 0.20 | 21. | 0.18 |
| Nitrate | 0.96 | 12.7 | 0.49 | 17.1 | 0.56 |
| Betaine | 0.22 | 161. | 1.4 | 36. | 0.23 |

¹Means are in mg/100 ml of extract except pol sucrose in percentage of sugarbeet root fresh weight. Amino N and total N expressed as N, and nitrate as NO₃.

These data do not differ greatly from a previously reported preliminary experiment (Sugarbeet Research, 1976 and 1977 Reports). Pol sucrose means of the two filtrates were almost identical, the correlation coefficient was above 0.99, and a paired-sample t-test showed no significant difference between filtrates. Sodium and potassium also were similar in means and had high correlation coefficients. Amino nitrogen was somewhat higher in aluminum-clarified filtrates than in the lead-clarified ones. As we have shown in another report in this volume, a purity predictive equation based on sodium, potassium, and amino N determined in aluminum-clarified filtrate is equally as effective as a similar equation using data from lead-clarified filtrate.

Because of interference to the nitrate specific ion electrode by the chloride salt used in this experiment, the apparent nitrate values in aluminum-clarified filtrates were erroneously high, but the correlation coefficient with nitrate determined in lead-clarified filtrates was high. Thus, as in the previously reported test, it appears that a nearly linear error of 35% overestimation exists because of chloride interference, and that an appropriate transformation of nitrate data in aluminum-clarified filtrates would yield results nearly identical to the data in lead-clarified filtrates. Although total nitrogen analysis in either of these extracts probably is meaningless, there was a moderate degree of association between the data. Only for betaine were data in the two filtrates not comparable.

WEED CONTROL IN SUGARBEET

Progress Report on Genotype - Herbicide Interaction Study; (BSDF Project 25).--G. A. Smith and E. E. Schweizer.

In the 1977 "Bluebook Report" page C17-18, we reported the initiation of a study to determine if genotype X herbicide interactions are a factor with use of several common pre- and post-plant herbicide treatments in sugarbeet. We tested five commercial varieties, five inbred lines, and five F₁ hybrids under three different herbicide regimes. In one of the sequential treatments, Ro-Neet was applied preplant at 3 lb/A followed by a mixture of Betanal (1/2 lb/A) and Betanex (1/2 lb/A) applied post-emergence. In the second sequential treatment, Nortron was applied at 2 lb/A followed by a mixture of Betanal and Betanex. A check consisting of all 15 entries was grown without herbicide treatment.

Data reported here is from 1978 which provided optimal moisture conditions for herbicide action.

For root yield numerous interactions were found among the 15 entries across the 3 herbicide regimes. Of most interest was the interaction of the 5 commercial cultivars with the herbicide treatments. Table 1 presents the rankings for root yield. Two of the cultivars (ACH 12, GW A₄) ranked relatively the same regardless of herbicide treatment, whereas HH 26 and Mono Hy D2 performed differently across the herbicide treatments. Beta 1237 yielded relatively poor under herbicide treatment but ranked near the top when compared under the hand weeded checks. Nortron reduced the root yield of the 5 commercial cultivars an average of 11 percent compared to the no weed competition check. Ro-Neet reduced root yield 4% compared to the check.

Interactions of F₁ hybrids and inbred lines with the herbicide regimes was much greater than for the commercial cultivars and reduction in yield compared to the hand weeded checks also were much greater.

Herbicide treatments caused slight reductions in sucrose % for inbreds, F₁ hybrids and commercial varieties.

Table 1. The relative ranking¹ for root yields of 5 commercial varieties under 3 herbicide regimes at Fort Collins, 1978.

| Variety | Ro-Neet B & B | Nortron B & B | Check (no herbicides) |
|-------------------|------------------|------------------|--------------------------|
| Mono Hy D2 | 2 | 3 | 4 |
| Am Crys 12 | 5 | 5 | 5 |
| Holly HH 26 | 3 | 2 | 3 |
| GW A ₄ | 1 | 1 | 1 |
| Beta 1237 | 4 | 4 | 2 |

¹1 = highest yield, 5 = poorest yield.

Control of Broadleaf Weeds in Sugarbeets with Glyphosate (Roundup); (BSDP Project 55).--E. E. Schweizer.

In the USA, growers can control 75 to 95% of their annual weeds in sugarbeets with herbicides, but this level of control is still unsatisfactory if we are to produce sugarbeets from the "tractor seat." Researchers have shown that a low number of weeds will compete with the crop and reduce yields. For example, root yields were reduced 8% by four kochia plants, 16% by twelve redroot pigweed plants, and 35% by twelve (equal densities) common lambsquarters, kochia, and redroot pigweed plants per 100 feet of row. At the latter density we found that 1.5 lb/A of Roundup, applied with a recirculating sprayer in 1977, reduced weed competition in sugarbeets to the extent that root yields were increased 7.9 tons per acre over where no Roundup was applied. Further, in Colorado, our best sequential herbicide treatments (preplanting plus postemergence) have had only 2 to 11 broadleaf weeds per 100 feet of row at harvest. Based on our results in 1977, we felt that the use of recirculating sprayers, or a modification thereof, may be the breakthrough that we need in the USA to control weed escapes from the "tractor seat."

The objectives of this study were to determine the effectiveness of glyphosate to reduce the competitiveness of a low density of kochia, common lambsquarters, and redroot pigweed in sugarbeets; and to determine the effect of glyphosate on sugarbeet root yields, percentage sucrose, and gross sucrose.

Materials and Methods. Diclofop (Hoelon) was applied at 1.5 lb/A on April 4 to control grass species. This herbicide was applied broadcast and incorporated with a Lilliston rolling cultivator at 4.5 mph. Pelleted Mono Hy D2 seed were planted on the same day at a spacing of one seed per 4 inches of row. Within two days after planting, an equal population of common lambsquarters, kochia, and redroot pigweed was established at a density of 12 plants per 100 feet of row. On May 15 we had to replant the sugarbeets. The sugarbeets were thinned on June 14 to a spacing of one plant every 10 to 12 inches.

The soil texture was a clay loam, with 2.5% organic matter, and a pH of 7.7. A randomized complete block design with four replicates was used. The plot size was 4 rows by 50 feet.

Commencing on July 3, the height of each weed was recorded in treatments 2, 5, and 7, and then thereafter every 4 weeks. In treatments 1 and 4, the height of each weed was recorded on July 19, and then thereafter every 4 weeks. On September 19, all broadleaf weeds from the center of each 2 rows were weighed separately by species.

On July 3, a recirculating sprayer was used to spray weeds above the sugarbeet canopy in treatments 2 and 5. The mean height (inches) of each species was: sugarbeets - 14, common lambsquarters - 20, kochia - 22, and redroot pigweed - 12. The lowest tip was 18 inches above the ground and the highest tip was 27 inches above the ground.

The sprayer was calibrated to apply 20 gpa on a broadcast basis and glyphosate was applied through four straight stream nozzles. Glyphosate

was applied once or twice at 1.5 and 2.25 lb/A (see Table 1 for specific treatments). Pressure was 13 psi and the ground speed was 3 mph. On July 3, wind was 0 to 5 mph at a height of 40 cm and the ambient temperature was 78 F. On July 17 the second application was applied to treatments 2, 3, 5, and 6. There was no wind and the average temperature was 83 F. On July 19 treatments 1 and 4, which received only one application of glyphosate, were treated. At this time the average height (inches) of sugarbeets was 18, common lambsquarters 41, kochia 39, and redroot pigweed 25 cm. The lowest stream nozzle was 22 above the ground.

On July 3, the total number of sugarbeets present in each plot was counted. On July 31, the total number of injured sugarbeets was counted. From this data the percentage of injured sugarbeets was calculated.

Sugarbeet roots were harvested from the inner two rows on October 13. The roots were counted, washed, weighed, and analyzed for sucrose content.

Results. Weed control. The effect of glyphosate on the three broadleaf weeds was not as effective as that observed in 1977. The principal reason being that the sugarbeets had to be replanted and the growth of the broadleaf weeds were set back because of cold, wet weather and from the mechanical disturbances caused by the planter. Glyphosate affected the average height and weight of these three weed species more than actually killing them (Table 1). Weed kill *per se* was minimal, and this was undoubtedly due to the fact that most weeds were just not tall enough to intercept enough glyphosate when it was applied.

Sugarbeet tolerance. The number of injured sugarbeet plants is shown in Table 2. Based on our visual observations, we found that 3 to 4% of the sugarbeet plants appeared to be injured even in the untreated weedy and weed-free plots. We are not sure why this occurred because we did not actually spray across the top of the sugarbeet plants in these plots; however, a drop of glyphosate could have occasionally fallen from a nozzle onto these plants as the sprayer was driven through the plots. Further, we observed that the 2.25 lb/A rate did not injure anymore plants than did the 1.5 lb/A rate, irrespective of whether the herbicide was applied once or twice. However, a few more sugarbeet plants were injured where we applied glyphosate only once instead of twice. We believe this occurred because where we applied the herbicide only once, we delayed the application until June 19 and the average height of the weeds was greater, thus we probably had additional splattering of the herbicide onto some sugarbeet plants underneath these larger weeds.

The effect of glyphosate on the yield parameters is summarized in Table 2. Glyphosate did not significantly affect percentage sucrose or number of harvestable roots. Further, glyphosate did not affect any yield parameter when applied at either 1.5 or 2.25 lb/A over the top of sugarbeets where no weeds were present.

Yield of both roots and gross sucrose was low because the sugarbeets had to be replanted. Even so, the competition of the density of 12 weeds per 100 feet of row reduced root yield and sucrose yield significantly in the untreated weedy-check plot. Since glyphosate did not completely control the weeds and injured sugarbeet plants initially, both root and sucrose yields were significantly less than the untreated weed-free controls.

Summary. Common lambsquarters, kochia, and redroot pigweed were not controlled satisfactorily by glyphosate. The principal reason being that the growth rate of these weeds was slower than what we normally have observed in previous years where we did not have to replant sugarbeets. We feel that because we had to replant the sugarbeets and because the growing conditions were atypical early in the year, we were not able to satisfactorily evaluate the efficacy of glyphosate rates and number of applications in this study. Therefore, we plan to redesign the herbicide sprayer for 1979 and repeat this experiment.

Table 1. Effectiveness of glyphosate treatments to reduce the height and weight of three broadleaf weeds^{a,b}

STORAGE ROT RESEARCH - 1978

W. M. Bugbee

U. S. Department of Agriculture, Agricultural Research
North Dakota Agricultural Experiment Station
Fargo, North Dakota

Two newly recognized storage pathogens in the Red River Valley

Storage rot was severe in some districts during the 1976-77 campaign. This probably was due to frost damaged roots and a crop grown under drought conditions. An unusual amount of Botrytis cinerea, an important storage rot fungus, was seen in the piles. There also was an abundance of mold, which appeared to consist of two different fungi. Rotted roots were studied in the laboratory. Penicillium cyclopium and Penicillium funiculosum were identified from these roots as members of the storage rot pathogen population. This is the first report of P. funiculosum as a sugarbeet pathogen. Both species were as virulent as Penicillium claviforme and more virulent than Phoma betae or Botrytis cinerea on two germplasms (F1001 and F1002) that were developed for resistance to P. betae and B. cinerea. They were less virulent on a breeding line (PBP4) that was selected for combined resistance to P. betae, B. cinerea, and P. claviforme (Table 1).

Table 1. Rot in root tissue from three sugarbeet germplasms (F1001, F1002, and PBP4) and one commercial cultivar (American Crystal 2 hybrid B, "2B"), caused by Phoma betae, Botrytis cinerea, Penicillium cyclopium, Penicillium funiculosum, and Penicillium claviforme.

| Pathogen | a/ Rot rating in host of given genotype | | | |
|-----------------------|--|-------|------|-----|
| | F1001 | F1002 | PBP4 | 2B |
| <u>P. betae</u> | 0.8 | 1.1 | 1.4 | 3.4 |
| <u>B. cinerea</u> | 1.8 | 1.6 | 2.6 | 4.8 |
| <u>P. cyclopium</u> | 3.5 | 3.0 | 2.0 | 4.8 |
| <u>P. funiculosum</u> | 3.4 | 2.9 | 1.9 | 4.9 |
| <u>P. claviforme</u> | 3.0 | 2.8 | 2.0 | 4.8 |

LSD = 0.9

p = 0.01

a/ Rot rating indicates the distance rot progressed through a 1-cm² block of root tissue after 2 weeks' incubation at 20° C: 0, 0 mm; 1 = not over 2 mm; 2 = over 2 but not over 4 mm; 3 = over 4 but not over 6 mm; 4 = over 6 but not over 8 mm; 5 = over 8 and up to 10 mm (entire block).

Pleospora bjoerlingii in the U. S.

Pleospora bjoerlingii is the perfect or sexual stage of the important sugarbeet pathogen, Phoma betae. The sexual stage has never been cultured and has been described three times in nature. All reports are from Europe.

Pleospora bjoerlingii, developed on seedstalks of sugarbeet after inoculation of the flowering plants with conidia of Phoma betae following harvest, and exposure of the seedstalks outdoors in Fargo. Single ascospore isolates were more virulent than a standard Phoma isolate on genotypes that had been developed for storage-rot resistance. The Pleospora stage was found on sugarbeet seedstalk stubble from each of seven fields that were sampled in the Salem, Oregon area where most of the domestic seed is produced.

The ability to produce the sexual stage on seedstalks will enable us to gain basic information about the mating cycle and inheritance of important characteristics. Production of this stage in culture in the laboratory would accelerate this work. Experiments are now in progress to accomplish this.

Sugarbeet seedling disease caused by Phoma betae on storage rot resistant genotypes

Sugarbeet genotypes possessing resistance to storage rot caused by Phoma betae were more resistant than a commercial cultivar to seedling disease caused by P. betae when inoculated seeds were grown in sand at 25C. Resistance was expressed as greater stand counts, greater plant fresh weights, less blackleg symptom, and a lower frequency of reisolation compared to the commercial cultivar. The amount of seedling disease caused by a set of isolates of the pathogen under controlled environment, showed variation in virulence among the isolates. An isolate that caused the most storage rot also caused the most seedling disease.

The results of some tests have not been duplicated. This failure may be due to uncontrolled relative humidity in the growing environment. Humidity has an affect on seedling disease development. A repeat of these tests in new growth chambers with controlled humidity will be done soon. Until then, conclusions from this experiment are that: resistant reactions in the seedling phase to P. betae do not indicate conclusively that a resistant storage rot reaction will be associated with the same material.

The data does show, however, that seedling disease resistance against P. betae is available so attempts to develop these genotypes should proceed because in some parts of the world, especially Europe, seedling disease caused by Phoma is much more important than storage rot.

The effect of plant age, storage, moisture, and genotype on storage rot evaluation of sugarbeet

Research since 1971 showed that evaluation of sugarbeet roots for storage rot resistance could be measured after roots were stored for at least 80 days at 5C. After storage, tissue cylinders are removed with a cork borer and placed on pure cultures of the test pathogens. Two germplasms with storage rot resistance were developed using this method. The availability of seed of resistant genotypes permitted a comparison with a susceptible genotype

regarding the effect of root maturity and storage environment on the response to major storage pathogens. The major objective of this study was to learn how to evaluate roots faster.

When sugarbeets were grown in 1976 under moisture stress, they became more resistant to rot caused by Phoma betae and Botrytis cinerea, but more susceptible to these fungi plus Penicillium claviforme when moisture was adequate. However, when aged roots of a susceptible commercial cultivar were stored at 5C for 80 days, those grown under adequate moisture in the fall of 1977 suffered less rot than those grown under moisture stress. It was concluded that: 1) 80-day-old roots could be evaluated for resistance to P. betae and B. cinerea in dry or wet years and to P. claviforme in wet years; and 2) differences between susceptible and resistant reactions will be as good or better than other storage regimes when roots are stored 30 days at 5C. This method shortens the growing period by 80 days and the storage period by 50 days and would be useful in identifying resistant roots in a breeding program from which new resistant lines are desired. Rot ratings, when averaged over root age and storage treatments, showed roots of a greenhouse-grown resistant genotype to be superior to a susceptible commercial cultivar. Thus, roots for evaluation may be grown in the greenhouse as well as in the field.

This shortened method requires 124 days compared to 254 days for the previous method. There are five advantages of evaluating 80-day-old roots: 1) less storage space will be required by the smaller roots; 2) sugarbeet roots must be vernalized for 80-120 days to induce flowering. The shortened method affords ample time to select, vernalize and obtain seed in the greenhouse before the next growing season; 3) two cycles of testing and seed production could be accomplished annually in the greenhouse; 4) storage rot information could be obtained from young, induced roots (stecklings) prior to seed production; and 5) a nursery could provide storage rot information before harvest of the main plots.

The effect of root dehydration on the storage performance of a sugarbeet genotype resistant to storage rot

Moisture loss from sugarbeet roots because of drought during the growing season or because of exposure to drying conditions after harvest causes the roots to become more susceptible to storage rot. Results from the USSR further show that cultivars resistant to storage rot maintain a higher leaf and root turgor than susceptible roots under drought conditions. Our objective was to determine the effect of water loss from stored roots on rot caused by the major storage pathogens in this region and to see if genetic resistance to rot would reduce sucrose losses under moisture stress.

The sugarbeet cultivar American Crystal 2 hybrid B (2B) was superior to the storage-rot resistant genotype 75P6 in the production of recoverable white sugar per ton (RWST) at harvest, but 75P6 was superior to 2B after the roots had been inoculated with Phoma betae, Botrytis cinerea, and Penicillium claviforme and stored at 10C in 98% relative humidity for 106 days. The amount

of rot in 75P6 was 50% of that in 2B when roots had lost 8-10% of their weight in storage. Dehydrated roots had a lower clear juice purity (CJP) and RWST than turgid roots. Severely dehydrated roots (24% weight loss) of both genotypes did not develop more rot than turgid roots (9% weight loss), but there was a decrease in pol sucrose, CJP, and RWST.

The quality deterioration of dehydrated roots during storage reported here, agrees with others, but our results show these losses may not be accompanied by increased rot.

Dehydrated and infected roots of 75P6 did not suffer an increase in rot over the turgid roots. In fact, there was no change in rot development within each genotype whether dehydrated or turgid. There was a significant decrease during storage in RWST, purity, and pol sucrose in dehydrated infected 75P6. It is possible that moisture loss, coupled with infected tissue, caused a sufficient increase in respiration in 75P6 to account for the decrease in sucrose content. There is a general phenomenon that infected, resistant plant tissue respire at a higher rate than infected, susceptible tissue. Therefore, the prevention of root dehydration during storage was more important for the rot-resistant genotype than it was for the susceptible cultivar.

SUGARBEET STORAGE - 1978

Darrell F. Cole

U. S. Department of Agriculture, Agricultural Research
North Dakota Agricultural Experiment Station
Fargo, North Dakota

Sugarbeet storage is a complex problem which will require changes in several areas to reduce losses to a minimum. The major loss of sucrose is caused by respiration, followed by microbial and biochemical changes such as raffinose synthesis.

Mechanical damage is a significant factor in the losses that occur by respiration. Mechanical damage to the beets occurs at several points during the harvest cycle, e.g., scalping, lifting, loading, unloading, and cleaning by the pilers. If mechanical damage is reduced, then part of the respiration losses would be prevented. The damage inflicted by scalping could be eliminated by removing only the leaves and petioles (flailing) and not cutting the crowns. Numerous reports have shown that flailing would reduce storage losses by decreasing respiration and by reducing storage rot.

The purpose of scalping is to remove tissue which has a higher concentration of impurities and lower sugar compared to the main body of the root. Data from Sidney, Montana, by Dr. A. D. Halvorsen showed that the amount of sugar extracted from crown tissue can represent over 20% of the total produced per acre depending upon the rate of nitrogen. Data presented by personnel of The Great Western Sugar Company have indicated that flailing reduces storage losses and recoverable sugar per acre is increased by flailing.

The objectives of this study were to determine the amount of crown delivered to the factories and its effect on quality. In 1975 and 1976 samples were obtained at several piler locations in the valley. In 1977 and 1978 samples were obtained at the Moorhead factory. Also, in 1978 samples were obtained at the Wahpeton factory. Two tare samples were obtained with the automatic sampler on the piler from each load. One sample from each load was used to determine the weight of the crown material above the lowest leaf scar that was delivered to the piler by the grower, and to determine the quality of the sample after complete crown removal. The remaining sample was used to measure quality of the roots as delivered. In 1975 and 1976 the samples were analyzed at the East Grand Forks Laboratory. The 1977 and 1978 samples were analyzed at the USDA Laboratory located at NDSU.

The data indicate that over 20% of the material delivered to the factory is crown tissue (Table 1). Percent sugar was not affected by complete crown removal in 1975, 1976, or 1977. In 1978, a significant change in percent sugar was noted at both Moorhead and Wahpeton when all of the crown material was removed. However, complete crown removal did not affect purity or recoverable white sugar per ton (RWST) at Moorhead in 1977 or 1978, but a significant change was noted at Wahpeton in 1978.

Table 1. Effect of complete crown removal on sugar, purity and recoverable white sugar per ton (RWST) over a 4-year period

| | 1975 | 1976 | 1977 | 1978 | |
|-----------------------|------|-----------|------|----------|----------|
| | | | | Moorhead | Wahpeton |
| Number of samples | 89 | 270 | 50 | 50 | 50 |

| Topped | - | - | 94.3 | 92.8 | 91.7* |
| | | RWST, lbs | | | |
| Control | - | - | 274 | 276 | 251 |
| Topped | - | - | 281 | 286 | 267* |

* Significantly different from control.

These data indicate that complete crown removal (over 20% of the material delivered to the factories) does not consistently affect quality. Data reported in the 1975 Sugarbeet Research and Extension Report showed that growers were removing 20% of the crown tissue produced by scalping. A survey was conducted at the Moorhead factory in 1977 to determine the size of the cut surface of the crown. Over 1,000 roots were selected from the "picking table" and measured over a 2 hour period. The data indicated that the average size cut was 2.4 inches. Use of the regression equation reported in the 1976 Sugarbeet Research and Extension Report to predict the amount of crown removed based upon the size of the cut surface showed that 20% of the crown had been removed by scalping.

The primary purpose of scalping is to reduce the impurity load in the factory. The data presented here and by others has showed that scalping probably does not substantially reduce the impurity load. However, all research has showed that scalping increases respiration and rot losses. In view of these two facts, a serious question can be asked about the validity of scalping.

A test was conducted with a grower in 1978 to determine the effect of flailing vs scalping of sugarbeets on yield and quality. A uniform field of 168 rows, 0.5 mile in length, was divided into three sections. Section 1 contained 56 rows defoliated and scalped by the grower using a 3-drum defoliator. Section 2 contained 64 rows defoliated with a 2-drum defoliator which went over the rows in two directions. Section 3 contained 48 rows defoliated and scalped the same as section 1. Each section was harvested with a 4-row harvester. Nine loads were obtained from section 1 and was delivered and sampled by the routine company procedure. Two loads for sugar, two for tare, and five not sampled. Sugar and tare samples were taken alternately from the 10 loads obtained from section 2 and 8 loads from section 3. The samples were analyzed by the normal procedure at the East Grand Forks Laboratory.

The data showed that there was no effect on yield or quality when the beets were flailed compared to scalped (Table 2).

Table 2. Quality and yield of flailed and scalped sugarbeets from a commercial field in 1978

| n | Sugar % | Nitrate | Conductivity | Tare % | Yield | | Gross Sugar T/A |
|-----------|-------------------------|---------------------|---------------------|---------------------|--------------|------------|-----------------------|
| | | | | | Gross T/A | Net T/A | |
| Flailed 5 | 16.82 [±] .42* | 4.2 [±] .4 | 5.2 [±] .5 | 3.8 [±] .3 | 20.74 | 19.96 | 3.36 |
| Scalped 6 | 16.42 [±] .24 | 4.0 [±] .4 | 4.5 [±] .2 | 3.7 [±] .4 | 20.99 | 20.23 | 3.32 |

* Standard error of mean, yield based on total tonnage of all loads delivered from each section of field.

Another experiment was initiated in 1978 to determine the change in RWST of flailed and scalped roots during storage. Roots of two commercial cultivars (approximately 5 tons of each cultivar) were obtained from a grower. The beets were defoliated with a 2-drum defoliator which went over the rows in two directions, lifted with a 6-row lifter into a beet cart, dumped into a small truck and transported to the laboratory. The roots of each cultivar were harvested separately. The roots were washed and three levels of topping were completed in the laboratory by hand with a knife. The topping treatments were: 1) no crown removed; 2) a 1-1.5 inch; 3) a 2-2.5 inch cut through the crown. The roots were inoculated with a spore suspension of 3 common storage pathogens and placed into perforated plastic bags. The bags were divided into two groups. Group 1 was stored at a constant 5 C (41 F) and group 2 was stored at 15 C (59 F) for 20 days, at 10 C (50 F) for 20 days and then at 5 C for the remainder of the storage period. The storage period will be 160 days. At 60 days after harvest a set of samples from each temperature regime were frozen at -18 C (0 F).

There were no significant differences in quality at harvest among the topping levels (Table 3). Cultivar 2 was significantly better than cultivar 1 for sugar, purity and RWST. This data supports previous conclusions that the crown tissue removed by scalping does not reduce the impurity load of the factories.

There were no significant effects due to topping level after a 40-day storage period within each temperature regime. However, the roots stored at the higher temperature lost more RWST than those at 5 C. The roots stored at 5 C lost 7.3 and 6.0% of RWST for cultivars 1 and 2, respectively. The roots stored at the higher temperature regime lost 15.4 and 16.7% for cultivars 1 and 2, respectively. These data indicate the importance of cooling the beets soon after piling. The benefit of lower respiration and less rot in flailed roots will become more apparent after a longer storage period.

Table 3. Effect of cultivar and topping level on quality at harvest and after a 40-day storage period averaged over two storage temperature regimes

| Cultivar | Topping level | Harvest | | 40-Day Storage | | Sugar | Purity | RWST |
|----------|-----------------------|---------|----------|----------------|---------|-------|--------|------|
| | | Sugar % | purity % | lbs | Sugar % | | | lbs |
| 1 | none | 14.4 | 93.3 | 248 | 13.4 | 91.6 | | 222 |
| | 1" | 14.4 | 93.3 | 248 | 13.0 | 91.7 | | 217 |
| | 2" | 14.2 | 93.3 | 245 | 13.3 | 91.4 | | 219 |
| | complete [†] | 14.4 | 93.3 | 248 | - | - | | - |
| 2 | none | 16.2 | 93.9 | 283 | 14.9 | 92.7 | | 254 |
| | 1" | 16.0 | 93.7 | 278 | 14.8 | 92.3 | | 250 |
| | 2" | 16.0 | 93.8 | 279 | 14.6 | 92.0 | | 245 |
| | complete | 16.3 | 94.7 | 289 | - | - | | - |
| c.v., % | | 3.8 | 0.8 | 4.9 | 4.1 | 1.0 | | 5.5 |

[†] A set of samples were topped to the lowest leaf scar at harvest. Crown tissue accounted for 26.7 and 25.0% for cultivar 1 and 2, respectively.

Growth Regulators on Sugarbeets

Yield and sucrose content of sugarbeet, *Beta vulgaris* L., are negatively correlated. Post-harvest losses of sucrose have increased because of longer storage periods. The objectives of this study were to determine the effect of growth regulators on yield and sucrose content at harvest and on post-harvest losses of sucrose. Gibberellic acid and maleic hydrazide were tested for 3 years. A cytokinin hormone and a leaf inhibitor were tested for 2 years. None of the compounds increased yield or sucrose content at harvest. Gibberellic acid significantly reduced sucrose content and increased impurities at harvest each year. Gibberellic acid increased the post-harvest respiration rates during storage at 5C and near 100% relative humidity. Maleic hydrazide reduced post-harvest respiration rates in one test. Neither the cytokinin hormone, or leaf inhibitor had any effect on post-harvest respiration rates. These data confirm that of other researchers in that none of the chemical compounds tested have consistently increased yield or sucrose content at harvest or reduced post-harvest storage losses.

Evaluation of Sugarbeet Hybrids

G. J. Hogaboam

The evaluation program in 1978 was cooperative with the Farmers & Manufacturers Beet Sugar Association and its member companies.

The sugar and purity analyses were conducted by M. G. Frakes, and Paul Pfenninger, Michigan Sugar Company. The percent sucrose, percent clear juice purity, and recoverable white sugar per ton were determined according to "A rapid and practical method of determining extractable white sugar, as may be applied to the evaluation of agronomic practices and grower deliveries in the sugarbeet industry", by S. T. Dexter, M. G. Frakes, and F. W. Snyder, as published in the Journal of the American Society of Sugar Beet Technologists.

Thirty-two hybrids, US H20 (as 2 entries), and US H21 were tested at the Saginaw Valley Bean-Beet Research Farm at Saginaw, Michigan. These results are reported as experiment 7.

SUGARBEET DISEASE INVESTIGATIONS IN 1978

C. L. Schneider and R. L. Sims

1. Test of fungicides for control of leaf spot disease (*Cercospora beticola*). Plots of commercial sugarbeet variety, US H20, each comprising one 5-m row, were planted on 18 May. Rows were 71.1 cm apart. Dried and ground sugarbeet leaves, infested with *C. beticola* were applied as inoculum to the foliage on 28 June. By 8 August, disease incidence was 100%. Commencing on 15 August, treatments were applied twice, - either on 14-day or 21-day schedule, - as foliage sprays with a hand-operated, CO₂- powered sprayer at 103.4k Pa and at the rate of 561 liters spray material/ha.

Plots were rated according to disease severity on 7 and 25 September. Inasmuch as the disease had become established prior to the first spray application, satisfactory disease control required eradivative as well as protective capability in a treatment. There were significant differences among treatments (Table 1). The following reduced disease intensity significantly below that of the untreated control: BayKWO9925W + ATplus 411F; Benlate 50W; BTS40542 25EC; Difolatan 4F; DPX 112-2 80W; DPX 164-2 74W; Mertect 340 F; Mertect 266 S; Orthocide 50W.

2. Screening test of fungicides for root rot control (*Rhizoctonia solani*). Single-row plots of commercial variety sugarbeet variety, US H20, each 5-m in length and spaced at 71.12 cm, were planted on 18 May. On 29 June, 14 treatments were applied as sprays in a 20.3 cm band along the plant rows with a CO₂-powered, hand-operated sprayer at the rate of 561 l of spray material/ha and at 103.4k Pa (15 psi). On 30 June, dried barley-grain inoculum of *R. solani* was applied mechanically along the plant rows and into the leaf whorls. Disease incidence and intensity were determined for each plot on 7 August and 13 October and expressed as percent root rot.

By 7 August, there were significant differences in percent root rot between most of the treatments and the untreated control (Table 2). By 13 October, there were also significant differences among treatments. Treatments most effective in reducing root rot included Bravo, DPX 164-2, Du-ter, and Terraclor.

3. Test of fungicides for root rot control (*Rhizoctonia solani*). Plots of commercial sugarbeet variety, US H20, each comprising two 10-m rows, were planted on 18 May at two locations. The preceeding crops at Locations I and II were sorghum and sugarbeet respectively. Fungicide treatments were applied on 29 June with a pair of modified tractor-mounted herbicide-type band-spray units. Each unit was provided with two hollow cone nozzles angled at 45° and two side shields 15.24 cm apart. Sprays were applied in a band along the plant row at the rate of 561 l of spray material/ha and at 103.4 k Pa (15 psi). Dried barley grain inoculum of *R. solani* was applied mechanically along the plant rows and into the leaf whorls on 30 June. By mid-July, symptoms of root rot were evident. On 11 August and at harvest time mean percent root rot in each plot was determined.

By 11 August, with extremely high disease intensity in untreated plots at

both locations, there were significant differences in root rot among treatments. At Location I, Benlate, Bravo, and Du-ter treatments consistently showed significantly less rot than the untreated control. At Location II, Bravo and Du-ter reduced root rot initially, but by harvest time none of the treatments were effective.

4. 1978 Seed Treatment Tests.^{1/}

In certain years, some seed lots produced in Oregon are heavily infected with the fungus, *Phoma betae*. Six fungicides were tested for efficacy in reducing *Phoma* seed infection. Most treatments were combined with Dexon fungicide, commonly used to control seedling damping off caused by black root disease fungi. Two seed lots of commercial variety US H20 were used: Lot A, produced in Oregon, with considerable *Phoma* infection and Lot B, produced in Arizona, with virtually none. The seed was treated with an aqueous slurry of each material. The following tests were then conducted: 1) a plating-out test of Lot A on water agar to determine degree of *Phoma* infection; 2) a seed germination test in sand; 3) a field test.

The plate-out test showed differences in *Phoma* infection among treatments (Table 1). The following reduced infection significantly below that of the control: Dexon + Captan, Dexon + BTS 40-542, Dexon + Terracoat, Dexon + Terraclor, Terracoat, Terracoat + Benlate. In the sand test, excellent germination occurred with all treatments as well as with the control. In Lot A, all treatments reduced seedling blight below the level of the control. Seedling blight in Lot B was considerably less than in Lot A. In the field test there was no difference in seedling emergence among treatments and between the two seed lots. Lack of *Phoma* damage is attributed to relatively warm temperature prevailing after planting, and negligible damage caused by soil damping-off fungi is attributed to dry soil conditions that prevailed. No phytotoxicity was evident with any of the treatments. Further testing of seed after one and two years storage is planned.

5. Effect of cropping sequence on *Rhizoctonia* crown rot.

This research was conducted at the Saginaw Valley Bean and Beet Research Farm in cooperation with D. R. Christenson, Michigan State University, Department of Crop and Soil Sciences. The experiment comprises four cropping sequences, two with 2-, 3- and 4-year rotations and two with 3- and 4-year rotations. Pre-harvest count of plants showing *Rhizoctonia* crown rot symptoms was made on 2 October.

Post thinning stands averaged 129 plants/100 ft of row with no significant differences among treatments. *Rhizoctonia* damage was evident as early as mid-June. Incidence of crown rot (av. 8.6%) was considerably higher than in any year since the experiment began in 1972. As the following table shows, crown rot incidence following corn was considerably less than following beans.

^{1/} Conducted in cooperation with R. C. Zielke, Farmers and Manufacturers Beet Sugar Association.

Abstracts of Papers Published in 1978

1. Schneider, C. L., R. L. Sims, and H. S. Potter. 1978. Report of 1976 tests of fungicides to control leaf spot, crown rot, and powdery mildew diseases of sugarbeet. In *Fungicide and Nematicide Tests* 33:65-66.

Efficacy of 21 fungicide treatments in controlling leaf spot (*Cercospora beticola*), 19 treatments in controlling crown rot (*Rhizoctonia solani*), and 26 treatments in controlling powdery mildew (*Erysiphe polygoni*) was determined in field trials with commercial sugarbeet cultivar, US H20. In each test, all treatments reduced disease severity significantly below that of the untreated control. The tests showed significant differences among treatments in control of leaf spot and powdery mildew. Extreme variability among treatments in the crown rot control test resulted in non-significant differences among treatments.

2. Schneider, C. L. 1978. Use of oospore inoculum of *Aphanomyces cochlioides* to initiate black root disease in sugarbeet seedlings. *J. Am. Soc. Sugar Beet Technol.* 20(1):55-62.

Methods for preparation and use of oospore inoculum to initiate experimental infection of sugarbeet seedlings with the beet water mold, *Aphanomyces cochlioides*, are described. Increased density of oospore inoculum produced increased severity of black root disease in seedlings. Oospore inoculum applied below the soil surface near seed level produced a more severe disease than did inoculum applied on the soil surface, and inoculum applied at planting produced a more severe disease than did inoculum applied 6 days later. Disease severity increased when the proportion of mineral components:peat in potting mixes was increased from 1:1 to 2:1 or more. Oospore inoculum usually remained infective after storage for more than 1 year at 4 or -9°C.

BREEDING SUGARBEETS FOR RESISTANCE TO BLACK ROOT
AND LEAF SPOT

G. E. Coe

Research work on sugarbeets at the Agricultural Research Center, Beltsville, Maryland, is directed toward varietal improvement of sugarbeets resistant to *Aphanomyces* black root and *Cercospora* leaf spot, important diseases in eastern United States.

Testing for Leaf Spot Resistance

A good leaf spot epidemic was obtained in the 1978 Beltsville Nursery. Results of this test are presented in Table 1.

TABLE 1. Results of leaf spot tests at Beltsville in 1978.

| Expt. No. | Description | Av. Leaf Spot Rating* | | | |
|--------------|---|-----------------------|-----------------|----------------|------------------------|
| | | No. Lines Tested | Av. of Lines | USH20 Check | Exptl. Hybrid Check |
| 1 & 11 | Black Root and Leaf Spot Resistant MM lines from Beltsville | 66 | 4.0 | 5.5 | 3.8 |
| 15 | MM Cold Temp. Germination Selections | 33 | 3.9 | 5.7 | 3.7 |
| 17 & 18 | MM Powdery Mildew Selec- tions | 50 | 4.6 | 5.4 | 3.8 |
| 17 | MM Growth Chamber Selec- tions | 16 | 4.5 | 5.3 | 4.0 |
| 3 & 5 | MM lines from E. Lansing | 96 | 4.4 | 5.4 | --- |
| 13 & 14 | MM Soil-Free lines | 66 | 5.0 | 5.6 | 3.8 |
| 2 | BRR-LSR mm lines from Beltsville | 33 | 3.6 | 5.2 | 3.7 |
| 4 | mm lines from E. Lansing | 46 | 4.0 | 5.3 | --- |

* 0 = No spots; 10 = All leaves dead.

It appears that selecting multigerm lines for ability to germinate well and rapidly at cold temperatures did not affect their leaf spot resistance. On the other hand, multigerm lines selected for resistance to powdery mildew or for large seedling taproot size in the growth chamber were not as resistant as comparable unselected black root and leaf spot resistant lines. The loss in one desirable characteristic (resistance to leaf spot in this case) as a res

of selecting for another trait is consistent with the experience of plant breeders working with various crops, and points out the necessity of continuing to maintain desirable characteristics when selections are made for new traits. The poor leaf spot resistance of multigerm lines from East Lansing is the result of the inclusion of *Rhizoctonia* resistant lines that weren't particularly leaf spot resistant. The soil-free multigerm lines from Beltsville are also poorer in resistance because they stem from garden beets that weren't leaf spot resistant. The present level of leaf spot resistance of these soil-free lines, however, is considerably better than it was several years ago when selection for leaf spot resistance in this type material was begun, and better than USH20.

Testing for Black Root Resistance

Black root resistance tests were conducted in the greenhouse in the winter of 1977-1978. Results of these tests are presented in Table 2.

TABLE 2. Results of black root tests at Beltsville in 1977-1978.

| Description | Black Root Rating* | | | |
|---|--------------------|---------------------|-----------------|----------------|
| | No. Lines Tested | Av. of Lines Tested | Resistant Check | Suscept. Check |
| MM progenies from Leaf Spot Selections | 105 | 100 | 100 | 110 |
| MM progenies from Black Root Selections | 207 | 101 | 100 | 109 |
| MM progenies from SP74409-7 | 135 | 99 | 100 | 111 |
| Lines from a Commercial Company | 16 | 121 | 100 | 124 |
| 1977 Ohio State Test Selection | 8 | 106 | 100 | 110 |
| 1978 " " " " | 10 | 114 | 100 | 129 |
| Exptl. monogerm hybrids from Beltsville | 19 | 104 | 100 | 120 |

* Minimum-Maximum possible ratings: About 78 to 132.
Low rating = high resistance to black root.

The severity of disease in these tests varies from experiment to experiment, but the ratings are calculated in relation to the degree of resistance of the resistant checks. However, when the susceptible check has a high numerical rating, the lines being tested have a higher than normal numerical rating. The last four groups in Table 2 were in separate experiments, whereas, the first three groups in Table 2 each encompassed several experiments. Hence, the items listed as lines from a commercial company, the 1978 Ohio State Test selection, and the experimental monogerm hybrids from Beltsville are probably a bit more resistant than the numerical rating indicates. In the lines from the commercial company there is

only a difference of "3" between their average rating and the susceptible check, hence they must be considered rather susceptible. On the other hand, the average of the eastern breeding lines (the first three items in the table) is about equal to the resistant check. The resistant check is much more resistant than USH20. The average resistance of USH20 in these tests is about 107 or 108. Under present field conditions, the yield losses caused by black root in our most resistant material is negligible. Just as in the case of leaf spot, it is necessary to continue testing for resistance to black root in order to eliminate somewhat susceptible lines which appear in the process of selecting for other traits.

New Monogerm O-Types

Twelve new monogerm apparent O-types were located in indexing progenies in the greenhouse in 1977-78. All except one appears to have enough leaf spot resistance to be commercially usable in hybrid combinations. They have not yet been tested for combining ability. Tests on the B & B Farm in Michigan of single-cross experimental hybrids of male-sterile lines of O-types from previous years indicate that the combining ability of these male-steriles is not particularly good. Only four produced within 10% as much sugar per acre as USH20. It is possible, however, that one or two of these might produce superior hybrids in 3-way crosses.

Selecting Seedlings for Increased Vigor in Growth Chambers

In the 1977 Sugarbeet Research Report, the results of growth chamber tests of experimental hybrids produced from pollinator lines selected in the growth chamber for seedling root size and high root weight to leaf weight ratio (TLWR) were presented. One of these, SP73514-01 X SP6822-0 GCS (growth chamber selected), was tested at Beltsville and at the B & B Farm, Michigan, in 1978. These results are presented in Tables 3 and 4.

TABLE 3. 1978 Beltsville nursery test results of experimental hybrid from growth chamber selection.

| Variety | Root Yield T/A | Sucrose % | Raw-Juice | | Gross Sugar Lbs. |
|---------------------------|----------------------|--------------|-----------|--------|---------------------|
| | | | Apparent | Purity | |
| | | | | % | |
| SP53514-01 X SP6822-0 GCS | 9.53 | 12.6 | | 79.70 | 2401 |
| SP53514-01 X SP6922-0 | 10.36 | 14.0 | | 83.43 | 2901 |

Unfortunately, no hybrid seed of SP53514-01 X SP6822-0 was available for nursery testing. However, there should be little or no difference in the productivity of SP53514-01 X SP6822-0 and SP 53514-01 X SP6922-0. Statistical analyses of the 1978 nursery test data were not available at this writing, but it appears that the pollen fertile parent produced by growth chamber selections has no better and perhaps even poorer combining ability than the line SP6822-0, from which it was selected. This also would mean that the results of growth chamber tests of experimental hybrids might not agree with results of field tests.

TABLE 4. B & B nursery test results of experimental hybrid from growth chamber selection.

| Variety | Root Yield T/A | Sucrose % | C.J. Purity % | Sugar/Ton Lbs. | Sugar/Acre Lbs. |
|---------------------------|-------------------|--------------|------------------|-------------------|--------------------|
| SP53514-01 X SP6822-0 GCS | 20.02 | 16.19 | 94.43 | 272.0 | 5433 |
| SP43514-01 X SP6922-0 | 22.17 | 16.41 | 94.74 | 278.5 | 6152 |

TABLE 5. Growth chamber test results of experimental hybrids produced from growth chamber selections.

| Hybrid No. | Female Parent | | | X | Male Parent | | | Rank | | | |
|---------------|---------------|--------------------|---------------|---|-------------|--------------------|---------------|----------|----------|----------|----------|
| | Sel. No. | Source Material | Sel. Class | | Sel. No. | Source Material | Sel. Class | Test #1* | | Test #2* | |
| | | | | | | | | Rt. Wt. | Leaf Wt. | Rt. Wt. | Leaf Wt. |
| 1 | 72 | SP6922-0 | I | X | C-3 | SP7622-0 | I | 1 | 2 | 3 | 4 |
| 2 | 81 | SP7622-0 | II | X | 72 | SP6922-0 | I | 2 | 3 | 1 | 2 |
| 3 | 72 | SP6922-0 | I | X | 93 | SP7622-0 | VII | 3 | 1 | 2 | 1 |
| 4 | 72 | SP6922-0 | I | X | C1 | SP7622-0 | X | 4 | 4 | 5 | 5 |
| 5a | 72 | SP6922-0 | I | X | 71 | SP6922-0 | II | 5 | 5 | - | - |
| 5b | 71 | SP6922-0 | II | X | 72 | SP6922-0 | I | - | - | 4 | 4 |

*Test #2 is a duplicate of Test #1 except that the reciprocal of the 5th hybrid in Test #1 was used in Test #2.

In another experiment, growth chamber selections were made among seedlings of SP6922-0 and SP7622-0 multigerm pollen fertile lines. Four classes of selections were made on the following basis:

| <u>Selection Class</u> | <u>Root Weight</u> | <u>Root Weight</u> <u>Leaf Weight</u> (TLWR) |
|------------------------|--------------------|---|
| I | High | High |
| II | High | Low |
| VII | Average | High |
| X | Low | Average |

Clones were made of every selected plant so that the plants could be crossed in bags in all combinations. Seed was not produced on all plants in the bags so that testing of hybrid combinations was restricted, and seed quantities limited testing to the growth chamber. Results of these growth chamber tests are presented in Table 5.

As can be observed from the table, there appears to be a relationship between seedling taproot size (actually, taproot + crown) and the taproot weight to leaf weight ratio (TLWR). The two tests, however, did not produce identical results. As might be expected, hybrid #4 involving a Class X selection (low root weight and only average TLWR) had rather small taproots and a rather poor TLWR. The poor performance of hybrid 5a and 5b (reciprocal hybrids) might be due to the fact that both had SP6922-0 as their source. The poorer performance of hybrid #1 in Test #2 as compared with its performance in Test #1 has no logical explanation other than chance occurrence of genetically vigorous individuals in Test #1 and genetically smaller individuals in Test #2. It should be noted that hybrid #3 had the best TLWR in both tests in spite of the fact that it ranked third and second, respectively, in root weight in the two tests. This might indicate that a Class VII selection with its average size root must have a genetically extremely small top in order to have a high TLWR. It may also be probable that under most field conditions (20,000 plants or more per acre), this hybrid (#3 in these tests) might outyield the others because of the greater photosynthetic efficiency of its leaves.

In conclusion, it may be said that the growth chamber selection method may be a means of improving sugarbeets genetically in root production, but that this might not necessarily result in higher yielding under field conditions.

Production of Soil-Free Sugarbeets

When the two experiments containing progenies of soil-free sugarbeets were harvested, the plot was relatively dry. For the most part, the roots were free from adhering soil, making selection difficult. The selected roots were so clean (probably less than one gram of soil per root) they were put in storage without washing. Of the 66 progenies in these two experiments, six were equal to USH20 in leaf spot tolerance, and the remainder were more resistant. Root weights were not taken in these plots, but estimates of root

yield were made. Ten progenies appeared to yield less than USH20, and eight appeared approximately equal to USH20 in root yield. The remaining 48 appeared to be better than USH20 (It must be remembered that USH20 is not particularly high yielding at Beltsville because of its susceptibility to leaf spot.) Sugar analyses and raw juice refractometer readings were made on the selected roots. Generally, both sugar percentages and percent of other solubles were quite low. This is due to the fact that this material stems from garden beet crosses, and material of this origin is notoriously low in % sucrose. A few individual roots, however, have a reasonable sugar content and are being saved for crossing with sugarbeets.

F₁ hybrids of crosses between selected soil-free beets (originating from garden beets) and smooth-rooted sugarbeets ("soil-free" selections containing no garden beet ancestry) were grown in the nursery in 1978. These hybrids were also reasonably free from adhering soil although not as clean as the roots described in the previous paragraph. Since they were just as clean or cleaner than smooth-rooted sugarbeets, and since crosses between soil-free beets and ordinary sugarbeets produce F₁ hybrids that have considerable adhering soil, it is reasonable to assume that genetic factors conditioning root types with a tendency to cling to soil have been largely eliminated from both smooth-rooted sugarbeets and from soil-free beets. The selected F₁ hybrids in the 1978 nursery were also slightly higher in sugar content and content of other solubles than were selected roots of soil-free beets. Hopefully, the F₂ population from these F₁ hybrids will contain individual segregates that are both extremely soil free and high enough in % sucrose to be usable.

Production of Homozygous Sugarbeet Lines

Completely homozygous plants can be produced by first obtaining haploid plants and subsequently doubling the number of chromosomes. One method of obtaining numerous haploid plants in certain species is to grow plantlets from anthers by sterile tissue culture techniques. We have been attempting to develop such techniques for sugarbeets. Within the last 14 months we have been able to obtain callus growth from flowers with anthers removed. From this callus we can promote the development of roots and development of plantlets. We have been able to transfer plantlets to pots containing soil and obtain normally appearing sugarbeet plants. The plants examined cytologically have thus far been diploid indicating that the original callus must have come from normal diploid somatic tissue. We have not yet discovered a medium which will cause callus or plantlets to grow from anthers. One medium has caused the anthers to enlarge to many times (perhaps 20 or more times) their normal size, and within the next year we hope to find a medium that will cause anther dyads to grow into haploid tissue. When this hurdle is cleared, we should be able to produce completely homozygous sugarbeet lines without difficulty. Such lines should be very useful as testers to determine more accurately the combining ability of potential parental lines of hybrid varieties. The production of haploids might also be a useful tool for eliminating lethal and deleterious genes.

Cold Temperature Seed Germination

A nursery planting was made in 1978 to determine if breeding lines selected for rapid emergence of seedlings at cold temperatures would emerge more rapidly in the field. Unfortunately, the weather turned warm at planting time and all lines emerged quite rapidly. There was no difference in speed of emergence between the selected lines and the unselected lines.
